These two cases, says M. Guibert, present striking analogies. We see the same cause, the sting of a spider, giving place soon after to symptoms of a peculiar evolution and certainly alike in the two cases—cramps, convulsive trembling, and troubles of variable gravity involving the muscular system only, followed by gastro-intestinal and renal symptoms which, says M. Guibert, may lead us to think that the poison was eliminated by the intestine and by the kidney. These two cases scarcely accord with what Laboulbène writes in an article on spiders in the Dictionnaire encyclopédique: "In these regions the venom of spiders does not produce any unfavorable effects, and I will prove it. Walkener allowed himself to be stung by the largest spiders, and, he says, without any pain, redness, or swelling resulting. These stings did not cause any marked sensation, not any more than that produced by the prick of a fine needle in the finger. The spider's venom is, then, very much less active in man than that of the bee, of the wasp, of the gnat, of the flea etc. In central France Dugès made experiments and allowed himself to be stung by large spiders. He did not believe in the noxiouslyness of their venom. The danger, he said, was imaginary."

We can not in any way, says M. Guibert, subscribe to this opinion; in the two cases mentioned the relation of cause and effect was too evident to be denied. He does not ignore, he says, that the objection may be raised that the real cause, the spiders, had escaped, for in spite of a careful search he was not able to find them, and he recognizes the fact that this is a flaw, but one for which he can not be held responsible, and it can not, unfortunately, be compensated for by the description given by the patients, who were the only ones that saw the spiders.

It is none the less true, however, says the author, that it should, in future, remain accepted that the sting of certain insects or spiders may produce positive symptoms, the gravity of which varies, it is true, and the situation of which is especially in the neuro-muscular system, extending subsequently to the excretory organs, causing various passing troubles. M. Guibert does not think it would be scientific, still less practical, to consider at the present time that these accidents belong exclusively to the domain of popular prejudice.

The Manufacture and Characteristics of Munich Beer.—The Lancet's special analytical sanitary commission has recently made an analysis of Munich beer, and made its report in that journal for February 16th. German beer, more especially the Munich beer, the commission finds, is undoubtedly becoming a very popular beverage in Great Britain. It is not "heady," and is both light and very cool. Those who can not do sedentary or clerical work after taking the strong and heavy English ales and stout are not inconvenienced by drinking lager beer. It is in every respect an excellent drink for the advocates of true temperance—that is to say, for those who are opposed alike to the intemperance of excessive drinking and to the intemperance of total abstinence. German beer ranks side by side with light natural wines, which French legislators now qualify as hygienic drinks. Of all German beers, that which is the most renowned and the most extensively drank in all parts of the world is undoubtedly the Munich beer. From time immemorial, says the writer, Munich has been renowned for its beer, and this reputation, so early acquired, may be due, in a measure, to the severity of the Bavarian laws in respect to the making of beer.

Apart from the laws restricting brewers to the use of malt, hops, and water only, there is another legislative reason why Munich beer should be of good quality. A tax has been imposed on malt since the year 1543. In the breweries there is a special apparatus which is sealed and kept under control by excise officers. The malt passes through a sort of revolving drum;
each revolution is recorded mechanically, and thus a correct account of the amount of malt that has gone through is obtained. The tax varies according to the quality of the barley employed; therefore there is nothing to be gained, so far as the tax is concerned, by using inferior qualities of barley. This malt tax being very high, it pays to have only the best quality of barley. There is another law, which, after repeating that beer shall be made only of hops, malt, and water, adds that it is especially forbidden to use barley that has not been converted into malt, or that is mixed, partly barley, partly malt. Thus this law has brought about the best fundamental conditions for the production of a really wholesome beer. One reason, says the writer, of the superiority of Munich beer is the great skill with which the barley is selected. It must have a definite amount of albuminous substances so as to produce a good fermentation, and it is not the barleys with the best exteriors that give the best results. It is, however, especially in the details of manufacture that the explanation of the excellence of Munich beer will be found. To understand the subject, therefore, says the writer, a visit to the leading breweries was necessary, and, as it was impossible to visit all these vast establishments, a selection had to be made, and the directors of the Lowenbrau, which stands at the head of the large breweries, gave every possible facility for the complete inspection of all the processes they employed in the manufacture of the most popular of German beers.

The writer gives here a detailed account of the process, and remarks that it will be seen that it differs greatly from that generally practiced in England, and that it is well calculated to produce a very wholesome beer. It will also be seen, he says, from these details that the great secret of Munich beer may be summed up in the one short word, "ice." This is the all-important secret for the production of really good, nutritious beer, which nevertheless contains very little alcohol. Great cleanliness and a very low temperature are the fundamental requisites. Formerly it was impossible to make beer in summer. Even now the smaller brewers brew only in winter, for it is only by the employment of very expensive machinery that a low temperature can be artificially created. On the other hand, a temperature which is the result of mechanical action can be much more precisely regulated.

With regard to bottled beer, after careful cleansing, and after being filled with beer and corked down by a patent airtight porcelain and rubber stopper, the bottles are pasteurized. This means the immersion of the bottles into a tank of water into which steam is discharged so as to bring the heat up to about 160° F., at which temperature the germs of a second fermentation are destroyed, and the beer can then be kept for an indefinite time and exported even to the hottest climates.

These are the main features of the manufacture of Munich beer, says the writer, as it was shown and explained to the commission at the largest brewery on the Continent. "We have seen," he says, "the salient points of difference between the English and German or Bavarian mode of manufacturing beer, and a knowledge of the processes which the Munich brewer employs throws considerable light on the observation that, while Munich beer serves admirably to quench thirst, yet it is devoid of those properties of English-made beer which have given rise to the proverbial saying that 'to drink beer is to think beer.'"

With regard to the analysis of the samples of the water, the yeast, and the malt, as well as the beer, the writer gives an account of the examination and the results, which, he says, are instructive in partly accounting for the differences of physiological cleft between English and Munich beer. Thus, in spite of the fact that the Munich beer contains a greater proportion of nutritious malt extractives than even the strongest beer mentioned previously in the report, yet the alcohol is reduced to almost exactly half the quantity contained in the English beer. It is, however, the influence of hops and that of alcohol which combine to produce dryness and stuper, so that we have at once, says the writer, a complete explanation of the advantages which the consumption of Munich beer affords in this respect. The reduction of these constituents, he says, is not effected at the expense of the important alimentary constituent of beer. On the contrary, the percentage of malt extract in Munich beer is slightly in excess of that in ordinary " mild" English ale. The nutritive value of malt extractives is due in part to dextrin and malt sugars, but the mineral matter, owing to its richness in phosphate, must add largely to the nourishing properties of the beer.

The final operations of analysis were devoted to the examination of the beer for hop substitutes and objectionable preservatives, and, says the writer, the beer was found to be entirely free from substances of this class, and the search for bitter substitutes was attended with similar results. In the light of these excellent qualities, he says, which the analysis has brought to view, we are justified in regarding the beer as not only genuine, but wholesome.

The New York Academy of Medicine.—At the last general meeting, on Thursday evening, the 7th inst., the special order was to be a discussion on Malnutrition, Practically and Physiologically Considered.

At the next meeting of the Section in Surgery, on Monday evening, the 11th inst., a paper entitled A Report of Thirty-five Cases of Amputation of Omentum in Hernia Operations, will be read by Dr. W. B. De Garmo. Pathological specimens, new instruments, and apparatus will be exhibited.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 12th inst., the following papers will be read: Strangulation of the Testicle and Epididymis from Torsion of the Spermatic Cord, by Dr. John Van der Poel; and Clinical Symptoms due to Chronic Prevesical Inflammation, by Dr. W. K. Otis. Cases will be presented and new instruments exhibited.

At the next meeting of the Section in Pediatrics, on Thursday evening, the 14th inst., the following papers will be read: The Use of Alcohol in Diseases of Children, by Dr. August Seibert, and Morphinism in Children, by Dr. J. B. Mattison, of Brooklyn.

At the next meeting of the Section in Orthopedic Surgery, on Friday evening, the 15th inst., Dr. T. Halsted Myers will read a paper on the Treatment of Fractures of the Lower Extremity by Apparatus designed to Shorten the Period of Recurrence. There will be a presentation of cases and patients, and new instruments and specimens will be exhibited.

The Astley Cooper Prize, of £300, will be awarded to the author of the best essay on diseases of the joints produced by syphilis and gonorrhoea. Essays, in English or accompanied by an English translation, should be sent to Guy's Hospital, London, before January 1, 1899, accompanied by the usual motto and sealed envelope. For further particulars, address Dr. Hale White, 65 Harlem Street, London, W.

A Definition of Influenza.—Dr. C. G. Carleton, of Lawrence, Mass., writes to the editor of the Boston Medical and Surgical Journal that a clergyman of his acquaintance defines the grippe as "a 'cold' possessed of the Devil."

The Yale Medical School.—The Boston Medical and Surgical Journal announces that the medical course of Yale University is to be lengthened to four years.
Original Communications.

SOME CRITICAL AND DESULTORY REMARKS ON RECENT LARYNGOLOGICAL AND RHINOLOGICAL LITERATURE.

BY JONATHAN WRIGHT, M. D., BROOKLYN.

(Third Paper.)

Wolf, in the Berliner klinische Wochenschrift, No. 31, 1894, again makes a very interesting communication concerning the patient examined several months ago before the Berlin Medical Society from whom he had extirpated the larynx, and who later obtained a very natural voice by the use of a modified artificial larynx. The patient lived two years and a half after the operation, and died of a metastatic growth in the right lung and another in the small trochanter of the right femur. The unusual and significant feature of the case was that there was no local recurrence, and this was vouched for by Virchow, whose statement is published in the same number of the journal. Such reports have excluded from our consideration almost all questions but one in regard to the treatment of any case of laryngeal cancer when first seen:

"Is it possible in this particular case to entirely remove the growth by a radical operation?"

The dangers of the operation itself are not to be considered for a moment. Death on the operating table is preferable to death by the ravages of laryngeal cancer. Where, however, there is extra-laryngeal infiltration discoverable such an operation is useless, and a palliative tracheotomy is about all that can be done.

I imagine that the sentiments of laryngologists have undergone a great change in this respect within the last few years. Dr. Cohen's case, lately shown in New York, was a very impressive object lesson.

This change in the laryngologist's opinion is well exemplified in Dr. Semon's experiences, which he is now publishing in the Lancet, December 15, 25, et seq., 1894.

Chiari's paper before the recent International Congress in Rome on the structure of the so-called fibromata of the vocal cords is published in the first number of the second volume of Fraenkel's Archiv. He finds that they are inflammatory and not neoplastic in origin, are frequently oedematous, and sometimes contain hemorrhagic extravasations.

The paper is not only very instructive in itself, but forms an illustration of how much work remains to be done in differentiating and properly classifying very many clinical manifestations of pathological processes in the mucous membrane of the nose and throat. It is a superficial, misleading, and dangerous proceeding, on observing various protuberances of these surfaces, to calmly describe them as fibromata, myxomatous, and angiomatica, when they are, in the vast majority of instances, nothing but different manifestations of chronic inflammation. It is superficial, because it is unscientific. It is misleading, because it gives a false idea of the frequency in the occurrence of true tumors. It is dangerous, because it thus forms a false basis for therapy.

It is very singular that the remarkable disease rhinoscleroma should be so closely confined to northeastern Europe and South America. It is supposed to be due to the bacillus of Frisch, but there must be other very important factors in its etiology or it would have become more widely disseminated. It seems to be not necessarily a filth disease, as it attacks by preference the peasants and rural population.

Secretan, in the Annales des maladies de l'oreille, etc., for July, 1894, reports two cases in brothers who lived in a lofty valley of the Valois Alps, evidence going to show that one contracted it from the other, but how it originated in the first case no conjecture can be formed, as they had never been residents of any locality remote from their home. Secretan also reports at second hand the history of two other cases in Switzerland.

In this connection it is of interest to read Sokolowski's account in Fraenkel's Archiv, vol. ii, No. 1, of cases of chronic hypertrophic laryngitis, in some of which the bacillus of Frisch was demonstrated and in some it was not. Clinically the difference was indistinguishable.

Sokolowski sums up as follows:

"1. The so-called hypertrophic subchordal laryngitis is in our country (Hungary) comparatively a rather uncommon process, which usually occurs among the country people.

"2. A clinical connection with the so-called blennorrhoea of Störk I could not establish in my cases.

"3. In the majority of the cases typhus fever appeared in their history. This seems to play a certain etiological rôle, as also appears from the observations of other authors.

"4. From a pathological, anatomical standpoint the process is to be regarded as a chronic hypertrophic inflammation, which ends in the formation of scar tissue. In a certain group of cases the specific bacillus of rhinoscleroma is to be regarded as the cause of the inflammation.

"5. Laryngo-fissure with deep excision of the proliferated part of the larynx, carried out as early as possible, is to be considered as the only proper treatment."

Fraenkel, in his paper on Paehydermia Laryngis, read to open the discussion at the International Medical Congress, and published in the first number of the second volume of his Archiv, adds little to our present knowledge of the subject. He, however, states for the first time, so far as I know, that Virchow exhibited a case, and gave the name to it before the Berlin Medical Society as early as 1860. Fraenkel maintains that his own explanation of the origin of the depression over the vocal processes in these cases has been supported by the majority of observers since Virchow's well-known paper in 1888 first drew the attention of laryngologists to the subject. The latter, it will
be remembered, ascribed this depression in the thickened mucous membrane at that point to its being there more firmly attached to the underlying cartilage. Frænkel says that it is due to the pressure of the opposite vocal process when they meet in phonation. The point is certainly trivial, but interesting from the fact that this depression had frequently been described as an ulcerative process or its scar.

Chiari, in the same journal, publishes a paper on pachydermia, also read in the discussion at the congress, principally on its clinical aspects. Incidentally he makes an interesting statement of his views in regard to the surgical treatment of tuberculous laryngitis. At the present time this is the most important therapeutic question with which laryngologists are especially concerned, yet one which apparently has hardly interested them enough in this country to give it a trial. Chiari says:

"Until Krause and Hereny published their results laryngologists were afraid to operate on these swellings [tuberculous infiltrations], because they rightly believed that tuberculosis of the larynx chiefly and essentially was influenced by the general condition of the patient. They therefore put their principal reliance in general treatment and made astringent or soothing applications to the larynx. They regarded energetic operations as hopeless, and more often as dangerous.

"But since Krause and Hereny have shown that the operative removal of the swellings and the curettage of their bases usually succeed well, these operations are now undertaken by all laryngologists, naturally nearly always only with palliative results, yet frequently also with complete local healing. . . . I need only here mention that although I have myself often tried all the methods [of operating] which are recommended, I only treat tubercular ulcers and infiltrations by operation—

1. When dyspnea exists, and where the stenosis can apparently be easily relieved by endolaryngeal operations; otherwise I prefer tracheotomy.

2. When dysphagia and hoarseness are caused by easily removable vegetations, and the general condition is not too bad.

3. When tuberculosis of the larynx manifests itself in the form of circumscribed infiltrations which can apparently be thoroughly removed, the patient being in good general health.

"But one must always remember that a radical operation is very difficult to carry out; that one can usually only bring about a temporary improvement; and that general treatment, tonics, etc., must always be given the first consideration; but one also frequently sees laryngeal tuberculosis remain stationary without local treatment; often under favorable general conditions it improves—yes, frequently even entirely heals."

It happens that in the August number of the Journal of Laryngology Hereny concludes his series of papers with thirty-two paragraphs of deductions from his experience. Some of these appear rather contradictory, and some of the recommendations, at least in this country, very impracticable at present; but it will be interesting to compare his indications for surgical interference with Chiari's. They are—

1. The tubercular tumors of the epiglottis.

2. In circumscribed chronic tumor-like infiltrations of the posterior wall of the larynx which show little inclination to break down.

"In chronic tumors resting on an inflammatory base, surrounded with proliferation products which resist all other methods of treatment.

4. In partial disease of the larynx, even when the epiglottis, false cords, and lateral ligaments are affected."

His contraindications are—

(a) In advanced plthosis of the lungs with hectic and wasting.

(b) In diffuse miliary tuberele of the larynx, or rather of the larynx and pharynx.

(c) In all cachectic conditions.

(d) In severe stenosis of the larynx caused by inflammatory swelling of the affected parts. In these cases tracheotomy must be performed as soon as possible.

(e) In patients exhibiting fear and nervous excitability, mistrust of a physician, and who are always changing doctors, especially those whose condition promises little hope of recovery."

This is all very discouraging. It reduces the number of suitable cases to so few that it leaves the problem of the treatment of tubercular laryngitis practically unsolved. When to these we add Hereny's further adjurations in regard to general treatment, which we instantly recognize as sound, the outlook is indeed dark. Nevertheless, it behooves us, as candid and unprejudiced observers, to encourage those who really have faith in it and the courage of their faith to give the method a fair trial. Certainly the sufferings of these patients can hardly be made worse. They all die without treatment and with other methods of treatment, or rather so few recover that it is hardly worth mentioning.

Capart, of Brussels, in the Belgian Society of Otology and Rhinology (Journal of Laryngology, December, 1894), recommends the surgical treatment of laryngeal tuberculosis, including electrolysis, and supports Krause, Hereny, and Gugnenheim especially, as to the good results in relieving the terrible pain. He also states that he uses tuberculosis with considerable success."

Mr. F. Marsh, of Birmingham, reported before the British Rhinological and Laryngological Association (vide Journal of Laryngology, August, 1894, p. 504) a case of Multiple Adenomatous Growths of the Larynx, etc.

Wolfenden and Martin, in their Studies on Pathological Anatomy, report a case. Gottstein reports a case in his work on the larynx, and Beale another in the Lancet for October 15, 1889, but these were accompanied by evidences of general lymphomatosis.

In a paper on Subglottic Neoplasms, published in the Journal of the American Medical Association for September 26, 1891, I reported a case very similar to Mr. Marsh's. These two, as far as I know, are the only ones on record
where local lymphoid hypertrophy has been demonstrated in the larynx.

Professor Fraenkel's demonstration of lymph nodes in the normal larynx, as reviewed in the first of these papers, explains the origin of these apparently rare growths. I say apparently rare, because both Mr. Marsh's case and my own had all the gross and clinical appearances of ordinary papilloma. I am convinced that, were microscopic examinations made of all these very common laryngeal papillomatous tumors, they would be found to be really, in many instances, something besides "papillary fibromata."

Dr. Arthur Sandford (ibid.) reported a case of death from convulsions six hours after scraping post nasal adenoids under cocaine. Mayo Coller also mentioned a case; and Lennox Browne said he knew of another. Some of those present were disposed to ascribe the unfortunate result to the cocaine. This may be doubted. At any rate, the trouble evidently was central. The case of wryneck recently reported by Dr. C. H. Knight before the Neurological Section of the Academy of Medicine followed an ether operation for adenoids. I believe that I have also seen such a case, but of a less marked degree than Dr. Knight's. I imagine that the trouble here is a local one, depending upon an extension of the traumatic inflammation into muscular sheaths near their origin at the base of the skull. A number of cases of hemorhage after adenoid operations have been reported, and several deaths; but it is a singular and striking fact that no case of sepsis has ever been noted after such a lacerating operation in this streptococcus-haunted and lymphatic-channeled swamp.

It is encouraging to observe what a hearty reception abroad the work of our health board in diphtheria has received. Dr. Park's and Dr. Beebe's paper was published in full in the Journal of Laryngology, and Dr. Wolfenden, in his address as president of the British Rhinological and Laryngological Association, mentioned it with high praise. Loeffer, in his address before the German Diphtheria Committee, at the Eighth International Congress for Hygiene, etc., in Budapest, spoke of the routine adopted for diagnosis by the New York health board as one worthy of imitation. There are very few men, even in our large cities, who have the requisite scientific training and special experience; there are very few laboratories in this country, with the requisite facilities, where reliable reports can be obtained. No doubt the example set by our health board will be followed in other cities in this country, successfully in some, but in many it is doomed at first to the mistrust that will arise from the mistakes of embryo bacteriologists. Time, however, will remedy all this.

The diphtheria antitoxine discovery is now passing through the hysterical stage in which sanguine vocation takes the place of prosaic proof. The tuberculin fracas is too fresh in our minds to allow us to do more than pray devoutly that it is all true.

Again attention is drawn to the rediscovery of an instrument by our transatlantic brethren. Ziem has described an electric nasal saw in the Monatsschrift f. Ohrenheilkunde, No. 7, 1894. We in America can not help smiling at the somewhat polemical tone he takes against gentlemen on the other side who published accounts of similar instruments in 1891 and 1892, when we look at the cuts of Dr. Roe's instrument in the Transactions of the American Laryngological Association for 1888, p. 205. Ziem's instrument is rather more crude, but of exactly the same design. The late lamented Dr. Potter, of Buffalo, also invented one. Dr. De Vilbiss has tried in vain, I am afraid, to adapt his electric saw to intranasal work. None of them are very satisfactory.

Smooth Atrophy at the Base of the Tongue and its Relation to Syphilis is a very interesting and careful paper, in vol. cxxxvii, No. 1, of Virchow's Archiv, by Professor Lewin and Professor Heller, of Berlin.

Tertiary syphilis, resulting in the degeneration and destruction of the glands at the base of the tongue, causing the so called condition of smooth atrophy, seems, from the records of the authors, to have been more often recognized post mortem than intra viam. As the affection rarely gives rise to subjective symptoms, as it is not always easy to recognize the condition in the laryngoscope, and as even palpation sometimes fails to reveal it, this is not to be wondered at.

Moreover, it is not pathognomonic of syphilis, for it also occurs, though less frequently, in non-syphilitic cases. In this connection it may be well to remark that Swain (and perhaps others) has shown that the lymphoid tissue, which has its chief site in immediate contact with the fibrous walls of these glands, is usually atrophied in phthisis pulmonalis and other wasting diseases. I have been repeatedly struck with the clinical rarity of lymphoid enlargements—those, for instance, of the faeual and pharyngeal tonsils—in tubercular cases.

The investigations of Lewin and Heller, and of others whom they quote, have shown that these lingual glands are relatively much more numerous to the square centimetre in children than in adults. The pathogenesis of the atrophy in these syphilitic cases is supposed by the authors to be due to previous syphilitic infiltrations which have started the atrophy by pressure.

The syphilitic infiltrations after a time disappear, but the glandular atrophy goes on. From my own histological observations in nasal pathology their conjecture seems extremely plausible. It will be interesting to observe now if clinical reports of cases follow this very carefully prepared dissertation, for, although Virchow first described the condition many years ago and it has since figured in his post mortem reports, and although others have occasionally mentioned it, attention has not heretofore been so prominently called to it.

Botey in his Spanish journal, Archivos Latino-Americanos de Rinología, etc., for August, 1894, publishes a paper on Paralysis of the Nose and Throat, which some of our radical brethren might read with profit and which others may read with pleasure. His conclusions may be transcribed here:
“1. Neurasthenies and those who are simply nervous and very irritable suffer sometimes from a sensation of oppression, of obstruction, of heat, of discomfort in the nose or back of the nose which hardly ever corresponds with any appreciable lesion.

“2. Pharyngeal parapathia is very much more frequent in these individuals, and is almost always localized at the level of the hyoid bone and at the base of the posterior pillar.

“3. Laryngeal and tracheal parapathia at the level of the cricoid and of the two first rings of the trachea.

“4. In neurasthenics with pharyngo-laryngeal parapathia are frequently found tonsils somewhat hypertrophied, granulations in the pharynx, varices at the base of the tongue, but in ninety per cent. of the cases, contrary to admitted opinions, after the most careful and energetic treatment of these material lesions, the trouble persists.

“5. It is to be noted that almost all of these parapathies present a certain amount, though to not a very marked degree, of pharyngeal and laryngeal anaphesia—that is, a more or less marked dyssyesthesiia or hypepathesia of these organs.

“6. Sometimes in these same patients there occurs slight suppression of secretion of those mucous membranes which at intervals appear less moist in places than ordinary, and rarely, even quite dry.”

I am sure a good many of us bear our candid Spanish confrere company in retrospective visions of futile on-slaughts on pharyngeal granulations, lingual tonsils, long uvula, and the like.

Lavrand, of Lille, in *La revue de laryngologie*, etc. (No. 16, August 15, 1894), sums up his studies of the distortion of the superior maxilla accompanying lymphoid hypertrophies in the pharyngeal vault as follows:

“1. In obstruction of the upper respiratory passages evidenced externally by the ‘adenoid facies’ the deformities are more apparent than real.

“2. The bones of the face and the maxillary sinuses are not modified in an appreciable manner in their development. If the cheek bones appear flat it is because the opening of the mouth drags upon the muscles, and suppresses thus the usual muscular protrusion which fills in the osseous depressions at this point.

“3. The external nose (hard parts and soft) which is flattened transversely, the superior dental arch, and the vault of the palate are the only parts which are actually deformed. The ordinary U-form of the arch frequently becomes a V from narrowing at the site of the premolars, because the cause exerts its action at this point. The retracted palatal vault takes the ogival form, but its depth has not really increased.

“4. The nasal fossa proper are not modified.

“5. These deformities of the external nose, of the arch and of the palate, have as a cause obstruction of the upper air-passages (nose or nasopharynx), and most frequently by adenoid tumors which make a more complete and more permanent obstruction than other lesions. There results from this habitual mouth breathing—that is to say, opening of the mouth and dropping of the inferior maxilla. I follow that the muscles of the upper lip and of the cheek are dragged upon—are stretched; they represent elastic bands which exert a gentle but permanent action upon the subjacent bony framework (external nose, superior dental arch, and palate), and tend to press them inward. The inferior maxilla suffers much less from this influence because it is more compact and more resisting.

“6. The deformities are more accentuated the earlier and more completely the obstruction is established.

“7. In order to prevent or correct these deformities it is necessary to re-establish as soon as possible the perme ability of the nasopharyngeal tract. Still more is necessary the obstruction removed, habitual nasal respiration will closure of the mouth should be obtained at any price, in order to suppress the action of the elastic bands.”

Lermoyez, in the *Annales des mal. de l’oreille*, etc., October, 1894, reports a case of post-nasal adenoid in an adult the ablation of which was followed by pulmonary tubercu lossis. This, however, was merely suggestive. Later operated on a child of six with a tubercular family history It was a poorly developed child and suffered from the symptoms of “adenoids.” The operation was soon followed by recurrence of the growths. A second operation followed, and this time the growths were examined microscopically and found to be largely made up of tuberculous tissue. The child recovered under hygienic treatment. In an Address on the Channels of Infection in Tuberculosis by G. Sims Woodhead, published in the *Lancet*, October 27, 1894, attention is strongly drawn to the cervical lymphatic, connecting the lymphoid material in the tonsils with the bronchial glands, as the channel by which the tubercle bacillus enters the pulmonary parenchyma. In very careful paper in Virchow’s *Archiv*, Band 138, Heft 3, Dr. Emil Krückmann shows that the cervical lymphatic becomes infected with tuberculosis either from the tonsils downward or from the glands at the pulmonic hilus upward by retrogression. The tonsils may occasionally be primarily affected, and through the cervical lymphatics infect the lungs; but in nearly all fatal cases of pulmonar phthisis he found that the tonsils had also become involved, and the evidence in many of the cases went to show that the primary infection was in the lungs, and that the tonsils became involved subsequently from the spatula passing over them. In some cases it was impossible to say which lesion was the primary one, the tonsillar or the pulmonar. In children, tonsillar infection was evidently frequently the primary lesion.

Clinically, the evidence all points to the facts observe by Krückmann at the autopsy table. In adults the infection seems usually primary in the lungs. In children the lymph nodes of the whole gastro-intestinal tract from the “pharyngeal tonsil” to “Peyer’s patches” are evident the absorbing spots of tubercular infection.

Dr. Cagny, in the *Lancet* for June 16, 1894, plunges into that bewildering maelstrom of laryngology and neurology, the much-debated question of abductor larynge
paralysis. Semon and Horsley, Dionisio and others, have pretty conclusively, at least in the present state of our dim knowledge, demolished Kraus's theory of contracture, but as yet they have been unable to explain why the adductor elements in the recurrent nerve and in the nerve centers are so much more vulnerable than the abductor. Dr. Cagney says it is presumably a matter of difference in nutrition. It has long been known that the nerve centers have atrophic or nutritional influence upon the nerves and muscles connected with them. Dr. Cagney says the abductor filament of the recurrent laryngeal nerve has been positively shown to have no cortical center, while all spinal nerve filaments have a cortical as well as a bulbar center. In this fact he sees an explanation or a hint to an explanation of the special vulnerability of the abductor apparatus of the larynx.

It will be remembered by the few who have followed the subject that Semon and Horsley demonstrated that extirpation of one cortical laryngeal center produced no effect on phonation, and that the stimulation of one cortical center produced double laryngeal motion. Masini has lately stated that with a weak electric current stimulation of one cortical center was observed to produce laryngeal motion only on the opposite side.

Semon has subsequently said that he had not been able to observe this, and now Onodi (Berl. klin. Woch., No. 48, 1894) says that he also has been unable to confirm Masini's statements in this regard.

Onodi then quotes Goltz as having reported extirpation of both cerebral hemispheres, the thalamus opticus, and the corpus striatum, in three dogs. They retained their phonautory motions in the larynx. Onodi, by a series of experiments on dogs, confirms this, and further says in summing up:

"The region whose preservation makes sound production possible extends together with the posterior elevations (of the corpora quadrigemina) eight millimetres. The upper boundary line is the transverse furrow which separates the anterior from the posterior elevations; the inferior line runs transversely across the surface eight millimetres below and behind the former. In this region eight millimetres in length a center exists which renders sound production possible, when the parts above are entirely severed. With a lesion, or an excision of this area, voice production stops and only inspiratory widening of the glottis can take place.

"Besides this I have produced lesions which were confined to one half of the fourth ventricle, including the region above the vagus center, which, however, produced no change in the voice formation of the living animal; the motion of the vocal cords persisted."

He suggests observations on the voice formation of asceptal monsters and subsequent post-mortem dissection. Some have been born alive and died after a few hours or days.

It is to be hoped that Our Animal Friends will not light upon this paper. It's "a long cry" to Budapest, but they might there gather some embarrassing data. The details of Onodi's experiments in this respect are related with a sang-froid that smacks of Oriental sentiments toward the lower animals.

Our old anatomical text-books used to teach us that the crico-thyroid muscle pulled the thyroid cartilage, the box of the larynx, down toward the cricoid, but now "nous avons changé tout cela," and we know that the cricoid and the trachea are pulled upward toward the thyroid cartilage which hangs from the hyoid bone and that from the inferior maxilla. Necessarily, we have been told, if the cricoid cartilage is pulled up the arytenoids which rest upon it must also be elevated. This confirms, we have been told, the laryngoscopic image which shows the elevation of the glottis during high notes and tension of the vocal bands. Now Newmann, in the Annales des maladies de l'oreille, etc., for November, 1894, says—and here I sympathize with him—that he has been puzzled to know why it is that in cases of paralysis of one vocal cord the affected arytenoid cartilage lies behind the sound side. He then shows very satisfactorily that while the anterior portion of the cricoid cartilage is raised by the action of the crico-thyroid during phonation and the adduction of the cords, the posterior part—that part lying behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid—is lowered. That, in other words, we have here a lever action with the hypomochlion at the crico-thyroid articulation, the power exerted on the long arm of the lever and the arytenoids or the weight on the short arm. Hence the contraction of the crico-thyroid, while it may raise the cricoid cartilage and the trachea, exerts its principal action anteriorly, while the posterior portion is lowered, at least in its relation to the thyroid. The fibers of the thyro-arytenoides are so arranged that their action on the vocal processes tends to pull them downward. Jelenfey has shown that some of the fibers of the crico-thyreo-arytenoides posticus when the cords are in adduction tend to pull the arytenoids cartilages backward, especially to tilt the tops of the arytenoids toward the rear. A study of the movements of the articular facets of the crico-arytenoides joints upon one another shows that in adduction the vocal process slides downward as well as inward. He says that the appearance of the paralyzed cartilage in the laryngeal mirror as lying below the sound side is an optical illusion due to the obliquity of the laryngeal mirror. The paralyzed cartilage lies in a plane behind that of the other, and seen from above looks lower, and this is still further accentuated by the cartilage being tilted backward so that its tip does lie in a lower plane than the tip of the opposite cartilage.

Newmann thoroughly supports his assertion by a number of very ingenious experiments upon dogs.

The Riverside Association.—We learn that this charitable organization, having an establishment at No. 259 West Sixtieth Street, has opened a hydriatic department where the poor will be treated without pay.

The Death of Dr. Daniel Hack Tuke, the well-known English alienist, is announced as having taken place in London on Wednesday, the 6th inst. He was sixty-eight years old.
CLONIC SPASM
OF THE TENSOR TYMPS.

By R. C. HEFLEBOWER, M. D.,
CINCINNATI.

This curious and obscure affection is but infrequently met with, and is one of the most interesting that the otologist has to deal with. It has been mentioned by some of the writers on diseases of the ear, and has been entirely ignored by others.

It was referred to as early as 1840 by Müller (1), who attributed the clicking noise observed to a contraction of the tensor tympani; Hyrtl (2), on the other hand, attributed it to a contraction of the tensor palatii. Politzer (3), in 1862, described it as a clonic spasm of the tensor palatii, as did Luschka (4) in the same year. Bock (5) reported a case in which there was an audiable clicking in the ear that was synchronous with a clonic movement of the soft palate and the larynx. Urbantschitsch (6) mentions a case in which he was able to stop the noise temporarily by making pressure with the fingers on the soft palate. In this case the noise could be heard at a distance of fifty centimetres. In another of his patients, lying on the right side would bring on the noise in the opposite ear. In still a third patient the noise was brought on by any fright and was present only when the patient was awake. This patient was a girl twelve years of age, and a year previous to the time of his observation had suffered from an attack of chorea minor. He attributes the noise to the clonic contractions of the tensor palatii. Schwartz (7), in 1867, made a contribution on clonic spasm of the tensor tympani. In the case reported he observed a sudden sinking in of the central portion of the membrana tympani and also that part situated posterior to the handle of the hammer; simultaneous with this there was a clicking noise that could be heard at a considerable distance. These occurred several times in quick succession, and after a short pause reoccurred. He noticed, also, the synchronous movements of the soft palate. Leudet (8) reported a case in 1869 that was associated with neuralgia of the upper maxillary nerve and facial spasm. Schwartz (9) says that in most cases there is the synchronous movement of the soft palate and the larynx, but there are also cases in which the affection is situated in the tensor tympani alone. In a case reported by Blau (10) there was neither a subjective nor an objective noise. Politzer (11) states that the hearing distance is lessened during the spasm. Burkner (12) has noticed spasm of the tensor tympani occur during catheaterism. He (13) refers to the affection as a clonic spasm of the tensor tympani, and says that in the majority of cases the cause is unknown. Moos (14) mentions a case in which each motion of the jaw in mastication caused a contraction of the tensor tympani. Walb (15) saw a case in which the noise could be heard the entire width of a room; this patient had suffered a hemiplegia of the left side which preceded the onset of the spasm of the tensor tympani; the sinking inward of the membrana tympani was observable in this case, and the implication of the soft palate was likewise present.

I have recently examined a case of clonic spasm of the tensor tympani, with all the throat complications present to a marked degree.

The patient is a woman thirty-five years of age, married, the mother of one child; she is in excellent health, and has had no illness for several years. In the right ear there is a chronic otorrhoea of many years’ standing. There is a large perforation downward and backward. Four weeks’ treatment has stopped the discharge, and the perforation is very much less in area. The hearing distance for the watch is an inch; for the tuning-fork six inches. In the left ear the membrane is a little lax; the reflex is absent; hearing distance for watch, sixteen inches.

The patient complains that she has had a clicking noise in the ears extending over a period of several years, and that this is accompanied by a twitching of the muscles of the throat. She states that it is becoming worse, and that it annoys her excessively; in fact, she comes to have it relieved and says nothing about the otorrhoea. It is worse when she makes any marked exertion, such as running upstairs, walking hastily, etc.; sudden fright will increase it to a great degree; it is worse at the time of the menses. On the other hand, it is only slightly annoying when she is quiet.

Upon watching the right membrane (the perforated one) no movement could be observed, although the clicking noise could be faintly heard. In the left ear, however, a very perceptible indrawing of the central and lower part of the membrane could be seen at the time of each click; the muscles of the soft palate contracted synchronously with the tensor tympani. The larynx is not in the least implicated.

It is worth while to note, in connection with this case, that her father was at different times during his life insane, and in fact died in an asylum.

In each ear the clicking is simultaneous with that in the other, and is never rhythmic. It comes at very irregular intervals, and is louder at certain times than at others.

Some time ago I saw another case of this same form of aural affection, and it was even more marked than the one I have just referred to, the sound being perceptible at the distance of two feet at times. The throat complication was also more marked, the larynx being markedly affected. This patient was a man of mature age, and was considerably affected mentally, verging, indeed, close upon insanity.

The point that strikes one most forcibly in comparing these two cases is the fact that the father of the first patient was a confirmed lunatic, while the second was himself bordering upon insanity. Is there any connection between the cause of the mental condition and the cause of the aural?

The etiology of this affection is indeed very obscure. That it is neurotic in origin there can be no question whatever. As to the exact form of the neurosis there is room for a difference of opinion. To my mind, the affection has all the characteristics of a distinct form of chorea minor. It is well known that adults may be affected with either of the forms, and that in many cases the mind is affected to a greater or less extent; it is likewise a well-known fact that in many cases of chorea there can be traced some neuropathic heredity, such as epilepsy, insanity, or chorea. In one of the cases, that of the girl, mentioned by Urbantschitsch, the cause was fright; this is likewise a not infrequent cause of chorea. Leudet’s case was associated with facial spasm, or “minischer Krampf,” which is a neurosis in nature allied to chorea. Charcot and S. Weir Mitchell
have described a hemiplegic chorea; might not Walb’s case, referred to above, have been one of this nature? We know that the pathology and the aetiology of chorea are well-nigh inseparable, and that the pathological anatomy is very obscure.

Let us look, for a time, at the nerve supply of the parts immediately and remotely involved in the phenomena connected with this affection. It may shed light on the nature of the disease.

The tensor palati and the tensor tympani both receive their nerve supply from the otic ganglion, which communicates with the facial and glosso-pharyngeal nerves through the small petrosal nerve and the tympanic plexus. Its motor root is received from the inferior maxillary branch of the fifth, and it communicates with the sympathetic system by a filament to the plexus about the middle meningeal artery. Meckel’s ganglion, which also takes part in supplying the muscles of these parts, receives sensory fibers from the two spheno-palatine branches of the superior maxillary nerve. It receives motor fibers from the facial nerve. It sends out four sets of branches—upward, to the orbit; downward, to the palate; inward, to the nose; and back, to the palate. The descending branches are distributed to the roof of the mouth, the soft palate, the tonsil, and the lining membrane of the nose. The Vidian nerve leaves the back part of the ganglion, passes through the Vidian canal, and gives filaments to the back part of the roof of the nose and the septum and that covering the Eustachian tube. The large petrosal branch of the Vidian ultimately joins the ganglionic enlargement of the facial.

The glosso-pharyngeal nerve also communicates with the facial by a branch just below the petrous ganglion joining the facial just outside the stylo-mastoid foramen.

Thus it will be seen that the communication between the nerves supplying the various groups of muscles in this region is at once intimate and complete.

Taking the several muscles concerned, we find:

Tensor tympani supplied by otic ganglion.
Tensor palati supplied by otic ganglion.
Tensor palati supplied by Vidian ganglion.

Azygos uvula .... supplied by Meckel’s ganglion.
Palato-glossus ....
Palato-pharyngeus.

Muscles of pharynx supplied by glosso-pharyngeal and pharyngeal plexus.

The accompanying diagram will make plainer the nerve supply of the various muscles.

This shows diagrammatically the intimate relations existing between these important nerve centers, and it can be very readily appreciated how anything that influences one might also influence the other. Thus, any pathological condition of the otic ganglion might act reflexly on Meckel’s ganglion, or, conversely, a pathological state of the latter might act in the same manner upon the former.

Intimately connected as these two ganglia are, it is more than probable that an affection of one is frequently associated with that of the other; thus, supposing elonic spasm of the tensor tympani to be an affection of the otic ganglion, it is well-nigh impossible that the tensor palati, which is supplied by the same ganglion, should escape. It is highly probable that the two muscles are involved simultaneously, though it will require more extended and more exact observation to prove this. Patients usually state that the ear is first affected, and subsequently the palate; but the chances are that the two are affected from the first, but that from the fact that the aural symptoms are the more pronounced they are supposed to have been first present.

It seems to me, then, that the elonic spasm of the tensor tympani and the muscles of the soft palate, and sometimes those of the throat, is due to a pathological condition of the otic ganglion, and frequently of Meckel’s as well, with occasional involvement of their branches of communication with other nerves. Whether this is secondary to preceding changes in other centers, which might also have an influence upon the mental condition of the patient, is a question that can not be answered at the present time, but it is possible that further investigation may determine it.

In this connection I may merely mention the fact that blepharospasm and certain twitchings of the orbicularis palpebrarum seem to be allied to spasmodic contractions of the tensor tympani, and the possibility of a connection between the two affections of entirely different sets of muscles. Owing to the communication between the facial nerve and Meckel’s ganglion, there may indeed be some direct connection between these forms of muscular affection.

As to the prognosis of this condition it is difficult to say much. It usually does not increase after a certain stage has been reached, and hearing is not seriously interfered with. The patient can be assured with a reasonable degree of certainty that it will not cause any marked degree of deafness, although any complication—such as chronic catarrhal disease of the middle ear—may impair the hear-
ing to a considerable extent; if this is present, it should of course be recognized.

In treating the affection, much has been recommended, including some very radical measures; but the results of all treatment have been slight. Proper hygienic measures are, of course, not to be neglected, and regular exercise, baths, etc., are a matter of importance. Arsenic is a useful remedy, and acts best in the form of Fowler's solution, and in fairly large doses. Bromide of potassium may be useful if there is much complaint of restlessness at night, general nervousness, etc. The constant current is of value if properly employed. To derive the greatest amount of benefit, one electrode should be applied just beneath the ear or behind it, and the other in contact with the soft palate or some point within the pharyngeal cavity. In severe cases it has been advised that the tendon of the tensor tympani be divided, but this would give only partial and temporary relief at best. Moreover, it has no influence on the pharyngeal portion of the trouble, which is often quite as annoying as the tympanic. Inflation of the middle ear is of occasional service, but it must be very frequently employed. The constant current and nerve tonics will perhaps do as much toward relieving the patient as any other course of treatment.

TWO CASES OF SEVERE POST-PARTUM HEMORRHAGE TREATED SUCCESSFULLY BY DR. R. H. M. DAWBARN'S METHOD OF SALINE ARTERIAL INFUSION.

BY V. H. MOORE, M.D.,
FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS AND SURGEONS, KINGSTON; MEMBER AND EX-PRESIDENT OF THE MEDICAL COUNCIL OF THE COLLEGE OF PHYSICIANS AND SURGEONS OF ONTARIO; SURGEON TO BROCKVILLE GENERAL HOSPITAL.

In November, 1892, I was called to attend Mrs. S. In her third confinement. She lived about four miles out of town. On my arrival at her house I found her in a dying condition. The child had been born, the placenta had come away, and flowing had followed until the woman had fainted and was almost completely exsanguinated. She was pulseless, semi-unconscious, muttering, with pupils dilated, features pinched, skin cold and bathed in perspiration, breathing rapid and gasping; in short, she presented all the symptoms of great loss of blood. I lowered her head, raised the foot of the bed, and placed the pillows under her feet and legs to keep them well up, not thinking it advisable at this moment to lose the time necessary to bandage her legs. I gave her full doses of ergot, whisky, and morphine hypodermically. removed a large number of clots from the vagina and uterus, irrigated the uterus with very hot water, filled the rectum with the same, and applied hot-water bottles to the body. The uterus contracted but the pulse did not return, the pupils remained dilated, the breathing grew worse, and death seemed at hand. The patient was so weak that I did not consider that the saline solution thrown into the cellular tissue would be of much if any value, and the time required for venous transfusion put it out of the question, so that to me there seemed to be nothing left but to try Dr. R. H. M. Dawbarn's method of arterial infusion. I had a small fountain syringe, also my hypodermic, with me, but no catheter. I hastily prepared the saline solution, making it very hot, considerably hotter than I could tolerate on my hand. I nearly filled the fountain syringe with the solution and placed it on a nail above the bed. I then felt for the femoral artery, which I could barely detect. I passed my hypodermic needle slowly and carefully into the tissues over the artery, watching intently for the arterial fluid, which soon appeared in the needle, when I cautiously placed the end of the rubber tubing over the needle and had my only assistant (a neighbor woman, who fortunately was endowed with a fair share of common sense as well as a goodly amount of courage) tie it firmly for me. The needle was now intrusted to this woman, whom I cautioned not to allow it to move in any direction. This instruction she faithfully carried out. I now examined the saline solution and, finding it hot enough, I raised the syringe or fountain about seven feet above the femoral artery. I kept the solution as nearly of a uniform temperature as possible by adding more of it from time to time of a higher temperature. I can not say just how much of the solution was introduced or how long the operation lasted, as I was too busy to pay much attention to time or exact quantities. It was good results I was looking for, and such were realized. The pulse returned slowly, the pupils contracted, the breathing grew better, the skin became warmer, consciousness returned, and my patient's life was saved. As soon as she had a fair pulse at the wrist I withdrew the needle. She made a good recovery, and never complained of any pain or soreness at the site of the introduction of the needle or in the course of the femoral artery.

My second case occurred on the 27th day of January, 1893, and was also a case of post-partum hemorrhage, quite as severe as the case just detailed. After the use of the remedies described in the former case I resorted to arterial infusion, with the same happy results. In this case my only assistant was a nervous and timid woman, and I was compelled to perform the operation as follows: As soon as the needle entered the femoral artery I seized it close to the thigh with a Tait's haemostatic forceps, using sufficient force to hold the needle firmly without injuring its lumen, the forceps lying on the thigh, handles toward the knee. Two or three strips of rubber plaster served to hold the forceps firmly to the thigh, rendering it impossible for the needle to escape from or penetrate deeper into the artery; in fact, it immobilized the needle almost perfectly, making the application of a rubber tube an easy matter, and leaving me free to look after the saline solution, pulse, or whatever might require my attention. I am fully persuaded that had I not made use of this rapid, easy, safe, and ingenious life-saving means, the product of the genius of Dr. Dawbarn, both my patients would have died.
FRACTURES OF THE ORBITAL WALL AND MARGIN.*

By H. McC. MORTON, M. S., M. D.,
OPHTHALMOLOGIST TO ST. BARNABAS HOSPITAL, MINNEAPOLIS, MINN.

Fractures of the orbit, irrespective of the interest they invite, as a study in themselves, are of decided importance viewed in the light of their relations to fractures at the base of the skull, associated or unassociated with injury of the cerebral mass, as well as their relationship to severe traumatism of the globe. There is a paucity of literature upon the subject of orbital fractures which renders it but a barren field to the bibliographer, while it adds much to the interest of the writer.

In the text-books upon ophthalmology the subject is conspicuous only by its absence, with the interesting exceptions of Noyes and Fuchs. In the American and English books upon general surgery, and in works devoted exclusively to fractures, few cases are to be found. The exceptions to these we note in a series of twenty-three cases reported in Helmitt's System, to which we may add nineteen cases reported by Berlin and a series of cases, with statistics, by von Hölder. Guthrie, in his very interesting Commentaries on the Surgery of the War, and McLeod, in his Notes on the Surgery of the Crimean War, throw much light upon and add much interest to orbital fractures resulting from bullet wounds, and their connection with injuries of the frontal lobes of the cerebrum. No particular classification of orbital fractures has been attempted, and yet such a classification is not alone justifiable, but is essential to a systematic study of this subject.

For a clinical study of these cases I shall consider—

1. Fracture of the orbital margin by direct force, and usually unassociated with severe injury to the globe.

2. Fracture of the orbital wall by indirect force, transmitted from the orbital margin or other parts of the skull, and usually associated with ocular injury or with injury to the brain.

3. Fracture of the orbital wall from direct force, usually spoken of as "penetrating fracture," and always associated with more or less severe injury to the globe or contents of the anterior or middle fossa.

It is my belief that almost all cases of orbital fracture can be properly considered under one of these heads.

Under the third division may be considered, very properly, those interesting bullet wounds, with but rare exceptions, occurring in war surgery alone, which enter the temples, pass through the greater wing of the sphenoid, and traverse one or both orbital fossae.

At this point it may be well to consider in a careful manner the particular liability of certain regions of the orbit to fracture, as well as the manner in which fracture is brought about. The conclusions I have arrived at are based upon experiments conducted upon a number of skulls, a careful study of most of the accessible reports of such cases, as well as the confirmatory evidence of a study of the bony anatomy of the orbital fossae. It may be noted that the outer orbital wall is the best protected, having the external angular process of the frontal bone and the frontal process of the maxilla bone as a buffer. Bodies striking upon this point are apt to be reflected upward upon the frontal, back upon the temple, or downward to the cheek. Force applied to the outer wall direct is apt to be turned aside to the apex. I do not believe that fracture of the lower wall or floor occurs from a blow upon the margin—at least it must be one of the greatest rarities. Fracture of the floor by direct force, usually a "penetrating fracture," is not uncommon, although less so than "penetrating fracture" of the roof. This fracture of the floor usually results from a piece of steel or wood or end of a cane projected with great force. If the force is applied in a line coming from the inner side of the orbit, it is likely to be deflected slightly and pass into the temporo-maxillary fissure, and possibly down into the temporal fossa, as has occurred in my experience. If the body is projected from the outside and downward and strikes immediately with the orbital rim, it is apt to pass direct into the antrum; but if applied to the floor farther back, is apt to pass to the apex and thus into the middle fossa.

Such an accident happened in the experience of Dr. William Pepper, and resulted in death from injury to a large meningeal artery. The inner wall is the most severely exposed to traumatism, lacking the deep ridge of the supra-orbital margin, which protects the superior wall, and the external angular process protecting the inner wall. Force applied here is very sure to be deflected to the apex unless the line of the projectile is almost perpendicular to the plane of the inner wall.

A study of the superior orbital wall or roof presents to us more interest than the others, as we shall see. Fracture of the roof may occur from direct force applied, as by a piece of steel or wood or point of a sword, by indirect force applied to the orbital arch at the region of the supra-orbital foramen or at the external angular process, or as a result of force applied to the frontal region of the skull. A body striking the roof is almost sure to pass through into the anterior cerebral lobe, since the plate presents slight resistance, and bodies striking the roof frequently come from a plane almost perpendicular to the roof; otherwise it is possible for it to be turned into the apex. Linear fracture at that point where it bends upon itself may occur from a blow on the orbital margin. This fracture is liable to take place into the frontal sinus, as in a case in my own practice, also in a case reported by Dr. D. Hayes Agnew. The liability of the orbit to fracture from blows upon the margin is better appreciated by taking up the skull and following the superior wall of the orbit by the finger with a tape measure beneath it. It will be observed in most skulls that the roof ascends in an almost vertical plane from the margin, and when about four to six millimetres from the base of the orbital cone turns upon itself to form the roof proper. A force applied at the supra-orbital margin will concentrate itself in a horizontal line at this bend. This happened in one case with me, and by experimenting upon a number of skulls I found that fracture is liable to take place here from indirect force applied to the margin.
as stated. Fracture of the roof may follow violent blows or falls upon the frontal region.

Agnew states it clearly thus: "In applying physical laws to the mechanism of the skull, we have the explanation of the fact that a blow over the frontal region, should it be foreiude enough to reach the base, will fracture the orbital plate or plates of the frontal."

The orbital plates seem to be the foci for this region of the skull as the petrous bones are for the middle fossa. Thus we may observe that fracture of the roof may result, in the first place, from direct force, usually producing a "penetrating fracture"; in the second place, by indirect force applied at the base of the orbit; and lastly, by force applied to the frontal region of the skull and concentrating itself in the orbital plates as a focus. Except in penetrating wounds of the orbit, the diagnosis of fracture is often obscure, and can be more easily inferred than positively demonstrated.

If, with a history of a violent blow at the orbital base or upon the frontal region of the skull, we have added the symptoms of ecchymosis of the conjunctiva, and sometimes exophthalmos, our suspicions may have some foundation. If followed by sudden blindness, we have strong evidence of fracture of the roof passing through the optic foramen. This has been pointed out by Berlin and von Holder, and is due to extravasation into the sheath of the nerve. This blindness is usually incurable. Similar symptoms may follow fracture of the base behind the orbit, but the symptoms are slower in making their appearance, as time is required for the blood to pass forward to the orbit.

Steele warns against putting too much stress upon ecchymosis as a symptom. He says: "Some think that the blood coming from the roof of the orbit always sinks and appears under the upper half of the conjunctiva, so that from such conjunctival ecchymosis, appearing several hours after an injury to the skull, we may diagnose a fracture of the roof of the orbit. Careful observation and experiment upon the cadaver have not entirely confirmed this. They show that a large amount of blood must be extruded and the periosteum torn for a fissure in the roof of the orbit to cause conjunctival ecchymosis."

Just how such experiments upon the cadaver could prove much I am unable to see. Any one of these symptoms, in conjunction with cerebral symptoms after severe injury in the locality of the orbit, would strengthen the diagnosis of fracture of the roof. These are the symptoms that may appear at or near the time of the fracture. In one case of mine, of fracture of the bend of the roof, there were no symptoms at the time, and it was two weeks after that a swelling was observed at the inner angle of the eye. This suppurated, and, when opened, a necrosis at the fracture was found. Cerebral symptoms may not appear until the removal of the body, and then may be followed by abscess, as in the case reported by Dr. Noyes, and also in a case which occurred in my experience as house surgeon at St. Luke's Hospital. After removal, inflammation set in and death resulted.

In "penetrating fractures" produced by a missile and with severe injury to the orbital contents or brain, diagnosis may be made by the finger passed into the wound made by the foreign body. It is possible that after withdrawal of the body the intense swelling may render the sinuses so tortuous as to preclude examination even with the probe.

Fractures of the margin are usually easy of diagnosis. The site of fracture is recognized by the unevenness and sensitiveness to pressure, and in extreme cases by crepitation. Fuhrn states that he has seen emphysema of the lids and orbit in such cases. If in the orbit, manifested by exophthalmos; but in this case the eye can be pushed back, while in the exophthalmos from extravasated blood this is not possible. Gauthrie states that after a wound of the frontal sinus the integument of the forehead was raised up when the patient blew his nose.

These fractures often fall upon the region of the orbit, or result from striking against the some flat surface, and are not usually from small bodies, such as cause fractures of the orbital wall.

In "penetrating fractures" of the orbit there is always more or less injury to the orbital contents, the globe or optic nerve usually suffering. In many cases enucleation is immediately demanded, since the tunics may be badly lacerated and the globe interfere with the removal of the body. In fractures of the margin, at the external angular process, we may have injury to the lacrimal gland, with abscess and subsequent fistula, as has happened with me.

Fractures at the inner orbit are apt to be attended with injury to the lacrimal sac.

Cerebral symptoms may occur from haemorrhage or from inflammation. Von Hölder has shown, after a series of observations extending over forty years, that a large majority of all fractures of the base are in, or secondarily extend into, the orbital plate of the frontal. Out of one hundred and twenty six cases of fractured skulls, eighty six were fractures of the base, and in seventy-nine the fracture involved the roof of the orbit. He states that in sixty-three of these seventy-nine, a fracture involved the optic foramen. Out of sixty-eight cases recorded by Hewitt of fracture of the base, twenty-three involved the orbit. Von Hölder, in his investigations, stripped away the dura completely and thus detected fissures that might not have been seen through the membrane. Yet a slight fracture may separate the dura from the bone, and by a rupture of the small vessels cause a haemorrhage.

Thus many cases of sudden blindness following a fall upon the head may be explained.

Penetrating wounds are in most cases unfortunately fatal, although we may have remarkable exceptions, for many of us have seen serious traumatism to the frontal lobe through the orbit, and with recovery.

In many cases of fracture of the orbital wall from the direct force of missiles the globe suffers entire destruction, the tunics being lacerated and the chambers filling up with blood. From such a fracture the internal carotid artery has been ruptured.

In these cases paralysis of the olfactory and oculo motor have been noted, and loss of the visual function from extravasation I have already spoken of. From adhesive inflammation the globe may be bound down to the perios-
Morton: Fractures of the Orbital Wall and Margin.

March 16, 1895.]

The lids may be badly lacerated or contused; in one case of mine almost the entire lower lid was carried away by the force of the large sliver. Cellulitis may follow also. In making our judgment as to the probable result of injury to the orbital wall or margin, we must be guided by the amount of injury discernible at the time, and by a full appreciation of all the possible complications, some of which I have just enumerated. We must remember that punctured fractures of the orbital roof are particularly fatal in tendency. Out of fifty-two such injuries reported by Berlin, forty-one died and eleven recovered. Of these eleven, three were hemiplegic, one had persistent headache, and one remained an amnemic, leaving but six complete recoveries. Of the forty-four deaths, fifty per cent. resulted from the immediate effects and fifty per cent. from subsequent complications. These statistics surely point a moral to us in our prognostications. In fractures of the wall by blows on the orbital margin or other parts of the skull, we must not forget the large percentage of fractures through the optic foramen and the danger of immediate or subsequent loss of sight. The treatment of these accidents must, of course, be based on general surgical principles. If the orbital margin is fractured and a resultant fistula remains from caries and necrosis, the channel may be enlarged and the dead tissue removed. In penetrating fractures with serious injury to the orbital contents, care must be taken that all the foreign body be removed if possible.

A case has recently come to my attention where, after the removal of the globe, the operator allowed a piece of the brass which had come from the gun causing the injury to remain in the retro orbital tissue. Two years after, he presented himself at my office with severe inflammation of the orbit. After manipulating with the finger I discovered this body, which was about three quarters of an inch long and half an inch wide. This may easily be avoided by carefully examining the apex of the orbit after removal of the globe—a manipulation that should be made a routine measure in the operation of enucleation. If the brain is involved, absolute quiet and general treatment after the removal of the body are indicated. Some of these cases may get along very well until an attempt is made to remove the body. Unless such a case as has occurred in my practice—of fracture at the bend of the roof into the frontal sinus, with caries and discharge—presents itself, as a result of a blow upon the margin, we may not be able to state whether or not there has been fracture. Arah states that with violent blows or falls upon the temporal parietal region, with symptoms of concussion, we have presumptive evidence of fracture of the base. This Ashhurst can not quite give his assent to. If this is true, however, we have the same evidence of fracture of the orbital plate after blows upon the frontal. But with severe falls upon the skull, with blindness, we have, I think, in the light of Berlin's investigations, good ground for diagnosing fracture of the roof with extension through the optic foramen, especially so with symptoms of concussion. Treatment here is expectant.

In fractures of the roof, with caries and subsequent external swelling or abscess, a free opening, I am convinced, should be made from the start, and the sinus followed up, enlarging, if necessary, and carefully curetting the dead osseous tissue. This, of course, with clear history of traumatism at such a point as might lead us to look for fracture. Free drainage should be established and kept up until all doubt as to a subsequent abscess forming has left.

Wounds of the lids should be stitched with silk, or simply with adhesive strips. I shall now consider under the distinct headings spoken of in my own experience and a few of other writers:

Case I. Fracture through the Orbital Margin.—H. H. M., aged thirty-two years, white. The patient presented himself at my office on March 21, 1894. On February 15, 1894, he was injured by falling against a car which was in rapid motion. He struck the frontal bone, also the rim of the orbit near the fronto-orbital articulation. When brought to me, his physician had succeeded in relieving him of all trouble, except a discharging sinus just below the outer canthus. A probe was passed up to the lacrimal gland, also to the seat of the fracture. Tear secretion came from the opening on the cheek and down upon the face. There had been a fracture just above the fronto-orbital articulation, the upper fragment being somewhat depressed and resulting in a prominence at the outer side of the orbit. With my friend, Dr. Eitel, assisting me, the sinus was freely opened up, some dead bone removed, the wound packed with strips of iodide of guaou, and the patient recovered. The point of interest about this case, aside from the fracture, was the sinus communicating with the lacrimal glands, and the direct discharge of tears upon the cheek. No extension of this fracture into the orbital wall was found, although carefully looked for.

Berry states that fracture of the orbital margin is rare. It has sometimes produced amaurosis, and it has long puzzled every one how such blindness was brought about. It is probable that some of these cases are due to an extension of the fracture to the optic foramen. In such cases we may have complete absence of ophthalmoscopic signs until the subsequent appearance of atrophy of the nerve or pigmentation of the retina. This is the only true case of fracture of the margin without further extension I have been able to find.

Case II. Fractures of the Orbital Wall by Indirect Force applied to the Orbital Margin or Skull.—J. A. L., aged forty years, white, consulted me on July 19, 1893. While passing out of a car he was thrown violently against an open door, which, by sudden stopping of the train, struck him over the supra-orbital nerve. Patient paid but little attention to it for three weeks, when a swelling at the inner canthus attracted his attention. This now, a month and a half subsequent to the injury, an abscess at this point. Painful and tender over the supra-orbital ridge. I did not think seriously of the fracture at the time. The pus was evacuated and the wound almost closed up when a new abscess formed; this also was evacuated. The discharge persisted, and at this time thinking that I could detect necrotic bone by the probe, I placed the patient under an anaesthetic and, with the assistance of Dr. Eitel, made a free opening at the inner angle of the eye up to the roof of the orbit. Here we found, at bend of the roof, a transverse fracture about an inch long. It was undoubtedly into the frontal sinus of that side. There was noticeable displacement of the posterior fragment, which was under the anterior. Some dead bone was removed.
and a tube introduced. The patient went on to an uninter-
rupted recovery. He has remaining a loss of sensation in the skin
over the region of the left orbit.

Case III.—A case spoken of by Dr. Agnew in his Surgery.
A sailor, who had fallen a hundred feet from the mast of a ves-
sel, when brought to the hospital had a wound over the right
malar bone. The man was unconscious and soon died. An
examination showed a separation of articularization of angular
process of malar with that of frontal, a fracture of orbital process
of malar, and also one extending across the roof of the orbit into
the frontal sinus.

Billroth reports a case of fracture of both orbitals and
extending through the sella turcica, following a fall upon
the head.

Guthrie thinks that the danger attendant upon injury
of the frontal sinus has been greatly exaggerated, and thinks
this fear vanishes in a degree when attention is paid to
their structure. It is probably the most fortunate place for
fracture of the orbital roof.

In this class of fractures we may or may not have at-

tendant external injury. McLeod speaks of the case of an
officer killed in the Crimean War; a round shot grazed his
head as it was reflected from the scale on his shoulder.
The scalp was almost uninjured, but so completely was the
skull smashed that its fragments rattled within the scalp, as
if loose in a bag. Over the margin of the orbit, injury to
the skin would seem almost necessary in such cases, yet in
the case of my own I have reported there was scarcely any
swelling for two weeks, and no cut at the time, yet the
force was sufficient to break the orbital plate. Neither was
there any ecchymosis—in fact, no immediate sign—and it
was two weeks before the first symptom appeared.

Fracture of the Orbital Wall by Direct Force or "Penet-
rating Fracture."—This is by far the most common form of frac-
ture to the orbital walls.

Case I.—D. D., aged twenty-two years, white. Saw the
case July 19, 1892. Patient was working about a saw, when a
loose sliver, five inches and a quarter long and an inch in di-

meter, struck just inside the lower orbital margin. The patient
was not unconscious at the time I saw him, one hour later,
and it was positively stated that he had not been so at the time of
or after the injury. After the patient was anesthetized, the
large plug of wood was removed with difficulty, being so firmly
wedged in. A large triangular fracture was made in the floor
of the orbit, and the posterior wall of the antrum was fractured,
allowing the end to project into the temporal fossa. The lower
lid was badly lacerated and partly torn away. A subsequent
operation was required to remove some small splinters that
were impossible to find at the time. The patient recovered
without complications, except a stiffness in the movements of
the lower jaw, which finally disappeared.

Case II.—Reported by Dr. Noyes. A boy, aged nineteen
years, was injured by the explosion of a gun. It was not known
that a foreign body had lodged until Dr. Noyes had seen him
five months after. He discovered the body—a sliver pin of the
gun, about four inches long, which had penetrated the nasal
cavity, passed through the floor and roof of the orbit, and
pierced the frontal lobe of the brain. Its presence had not been
indicated by any cerebral symptoms whatever. It was removed,
and fourteen days after, an abscess formed. The skull was tre-
phined and a drainage-tube passed from the trephine pole to
the orbital opening to give exit to pus. The boy died thirty-nine
days after its removal. This case is of interest for the length
of time the body remained without symptoms and death fol-
lowing removal.

Case III.—Reported by Dr. Noyes. A boy, aged fifteen
years, had the roof of the orbit penetrated by a large meat hook.
Recovery with loss of vision.

Finally, I may mention those cases occurring in war
surgery, principally where the bullet passes through the
fore part of the head, going through both orbits, and with-
out much mischief except loss of sight.

Guthrie speaks of four such cases in which the recovery
was rapid, but blindness irremediable. I have seen one
such case, in which there was no symptom except loss of
sight and most peculiar ophthalmoscopic pictures in both
eyes.

I have merely cited a few cases, not desiring to take
unnecessary time, in order to illustrate some of the points
spoken of in the beginning of this article.

It has been to me a great pleasure to speak of this sub-
ject before you, and if some of my statements seem arbi-
trary, I shall ask you to consider that I have had no essays
on this subject to guide me, and have only made such divi-
sions as seemed to me essential in the consideration of
fractures of the orbital wall.

THE HISTORY OF THE
TREATMENT OF SPONDYLITIS AND SCOLIOSIS
BY PARTIAL SUSPENSION AND
RETENTION BY MEANS OF PLASTER-OF-PARIS BANDAGES,
Together with the Present Status of this Plan of Treatment
before the Profession of the World.*

By LEWIS A. SAYRE, M. D.

When any new mode of treatment is advanced in
medicine or surgery, its advocates are apt to be overen-
thusiastic, and many of their readers, misled by apparent
brilliancy of immediate results, often fall into extravagant
praise, which further investigation leads them to modi-
fy; and, at times, discoveries which have been heralded as
striking boons to humanity have afterward been so com-
pletely forgotten that subsequent investigators have sup-
posed them original when they rediscovered them for a
second time, as was so admirably shown in the historical
sketch of spinal supports read before you last year by Dr.
Phelps.

It is now twenty years since I first applied plaster-of-
Paris jackets for the treatment of Dott's disease and lateral
curvature of the spine, and when your president did me the
honor to ask me to read a paper before you, it seemed to me
that I could find no better way of occupying your time than
by presenting for your consideration a résumé of the origin
of the plan, and of the opinions of the medical profession
of the world at large in regard to this mode of treatment
after this lapse of time. That the treatment has not re-
ceived universal acceptance is plain from a reading of the

* Read before the New York Academy of Medicine, January 31, 1895.
medical journals, though, in my opinion, the objections which have been advanced against it are, for the most part, due to a lack of comprehension on the part of the objectors of the principles which I have advocated, and their failure to properly carry out the mode of applying these principles; while, on the other hand, some of the more enthusiastic advocates of this method have gone to the other extreme, and claimed for it more than I have ever asked. As twenty years have now elapsed since I first practiced this method of treatment, it may not be without interest if I briefly review the manner in which I first came to adopt it.

For many years I was in the habit of treating most of my cases of Potter’s disease with the “Taylor brace.” I used to treat those who were too poor to pay for the instrument by applying what I called the “turtle shell” to the back.

This was made by laying the child on its belly across my lap, with the legs hanging over one side and the arms over the other, I then separating my legs so as to extend the spine and straighten it as much as possible, and until the child was perfectly easy and comfortable, which was made manifest in many cases by the improved respiration and the disappearance of grunting or jerking of the diaphragm.

While the child was held in this position a piece of linen or cotton cloth was accurately cut and shaped to the entire back, and two thirds around the entire trunk. In cases where the disease was in the cervical region the cloth was cut to extend to the top of the back of the head. Two or more pieces of cloth cut after the same pattern were then dipped in a mixture of plaster of Paris and water and laid smoothly over the first one. In the cases where the disease was in the cervical vertebrae, several thicknesses of this plaster bandage were put on the back of the neck, to give firm support to the head. Another piece of the cloth cut on the same pattern was then placed over the whole, and, while the spine was well stretched by separating my legs, an assistant applied a smooth roller bandage around the entire body and head, fitting it nicely into all the irregularities, and especially over the crest of the ilium, thus giving perfect support and preventing any motion of the spine.

When the plaster had become set, the child was then laid in the “turtle shell” on his back on a pillow, and the mother could sew a neat-fitting front to the sides of the plaster shell, and, lacing it in the center from pubes to sternum, make it give firm support to the spine, while at the same time it could be removed for purposes of cleanliness.

In very many cases this simple plan of giving rest to the spinal column was attended with very satisfactory results, especially where the disease was in the cervical region, in which location, if the head and neck had been well extended while the plaster bandages were applied, and retained in this position till the plaster was set, the weight of the head was removed from the neck and supported by the shoulders by the closely fitting plaster cast, and at the same time the whole spine was absolutely immovable—that is, no movements could take place between the separate bones.

In November, 1874, a little boy was brought to me having a sharp posterior curvature of the last three dorsal and the first lumbar vertebrae, and there was also partial paralysis of the rectum and one leg. As it was impossible to send the child to the hospital, as he did not live in the city, and I had no time to apply the “turtle shell,” I felt compelled to devise some plan by means of which the boy could be made comfortable while being transported to his home at Chatham Four Corners, Putnam County, New York, nearly one hundred and fifty miles distant. Having studied the subject for some time, and questioned myself regarding the propriety of completely incasing the trunk with a plaster dressing, I had finally resolved to make the experiment as soon as a suitable opportunity was offered. It seemed to me that the opportunity had then come, and that the circumstances justified the measure. Accordingly, I directed one of my assistants to suspend the boy by the arms in order to see what effect would be produced, and I noticed that, as soon as the boy was made pendent, there was more motion in the paralyzed limb than before, that the girdling pain around the belly was very much relieved, and that the patient was breathing much easier. While he was suspended in this manner, I pulled down his shirt and tied it between his legs, thus making it fit the body closely and smoothly, and then took some plaster-of-Paris bandages which had been prepared in the ordinary manner to be used in the treatment of dislocated ankle joints, and, commencing at the pelvis between the trochanters and the crest of the ilium, completely encircled the entire trunk to the axilla. At first I was anxious concerning the effect that would be produced upon the respiration, but, inasmuch as the boy cried lustily, all my fears in that direction were quickly dispelled, and I went on, reversed the bandage, brought it back to the pelvis, and so went on until four or five thicknesses of the roller were made to completely embrace the body. He was kept suspended by the hands of my assistant for about twenty minutes, until the plaster of Paris became hard. He was then laid upon his face on a sofa, and was to remain there until the plaster had become firmly set. I left him upon the sofa and went to my lunch, and when I returned, I found, to my complete astonishment, that the little fellow had got up and walked across the office, and was then looking out of the window. Still fearing that respiration might be interfered with too much, I cut through the dressing from the top of the sternum to the pubes, thus allowing it to gap considerably and permit of a more complete expansion of the chest. The boy, however, did not feel as comfortable after as before the incision through the front part of the jacket was made. I then applied a roller bandage around the pelvic portion of the jacket and again brought its edges together, but left the upper portion to separate as much as the movements of respiration seemed to require. In order to give security to the upper or thoracic portion, and at the same time to permit free expansion of the chest walls, I took the mother’s elastic garter, cut it into six strips, fastened them upon each side of the slit in the jacket, and then tied them in front.
The dressing now being completed, I requested the parents to return with the child at the end of a week or ten days, when I would have a Taylor's brace ready and would adjust it. The plaster jacket had been put on simply for the purpose of rendering the child comfortable while being carried home. That was the last I saw of either the child or the parents until the following February, four months and a half, when he again returned.

In the meantime the boy had grown considerably, looked healthy, was able to walk without assistance, and was not obliged to support the upper portion of the trunk by placing his hands upon his knees. Without waiting to make any further examination, I at once took the patient in my carriage and started for my clinic at Bellevue Hospital Medical College. The streets were covered with holes and elevations formed by the ice and snow, and the jolting was almost intolerable, yet the boy made no complaint whatever. That fact of itself showed how efficient the dressing was for securing absolute rest to the diseased parts. At the college the jacket was removed in the presence of the class, when it was found that the curvature was much less, but now the boy was unable even to sit up. As soon, however, as the dressing was reapplied, the mother remarked: "He can now sit up and walk again."

This, in brief, is the history of the first case in which I applied the plaster dressing completely around the body from the pelvis to the axilla. Since that time it has constituted almost the only treatment which I have adopted for Pott's disease.

The Proper Manner of Applying Plaster-OF-Paris Bandages in Spondylitis.—Crossbarred muslin or erinoline should be the material used in making the bandages. Frequently the kind of sizing used in the manufacture of this muslin prevents the plaster from setting quickly. It should therefore be washed to get rid of the superfluous sizing before being torn into strips from three to four inches in width and three yards in length. Of course the selvage is to be torn off. These strips are drawn through a tray filled with freshly ground plaster of Paris, and enough rubbed into the muslin to fill all the meshes. The bandages are then rolled moderately tight and laid in an air-tight tin until required for use.

The patient should have the body covered with a tightly fitting knitted or woven woolen sheet, without sleeves, tied tightly over the shoulders and drawn down and securely pinned over a folded towel in the perineum. For this purpose a safety pin should always be used. If the patient is a female, pads of proper thickness should be placed over the mammae and under the shirt, which pads are to be removed when the plaster sets, thus preventing pressure on the glands. Another towel, folded in such a shape as to cover the stomach and bowels, called the "dinner pad," which also is to be removed after the plaster sets, is placed inside the shirt, thus providing space for the expansion of the stomach during the process of digestion. If the patient has partaken of a hearty meal just previous to the application of the plaster, this dinner pad may be omitted.

The patient, being now prepared for the application of the plaster, is placed in the suspending apparatus, which has been heretofore accurately described in my several works on this subject, care being taken that the traction be evenly divided between the head and axilla.

Traction is now made very slowly and gently, and only carried to the point of giving the patient perfect comfort, and never beyond that point.

In some cases the heels will be slightly raised from the floor before this point is reached, but in many instances the heels will not be raised from the floor at all; and as the sensations of the patient are the only guide as to the amount of traction needed, an anæsthetic should under no circumstances ever be given, as has been done by some surgeons, as one requires the intelligent co-operation of the patient himself in regard to the amount of traction required. If it is a child not old enough to talk and tell its feelings, watch carefully the expression of its countenance; and when it is changed from pain to pleasure, there stop, never making traction beyond that point, and immediately apply the plaster bandages with great care and accuracy, pressing them into all the irregularities and covering the entire trunk from the pelvis to the top of the sternum.

If the patient is kept suspended in this position till the plaster is set, it will retain the body in the position of perfect comfort which suspension has given it.

In applying the bandages, one should be placed on end in a basin or pail of tepid water, deep enough to completely submerge it, when bubbles of gas will at once begin to escape. As soon as the bubbles cease, the plaster will be all moistened and the bandage ready for use. Do not add salt to the water as it renders the plaster brittle. Squeeze out the superfluous water before applying it, and place another roll, end up, in the water, which will be ready for use by the time the first one has been applied, and proceed thus until the entire jacket has been completed. The reason for placing the bandages on end in the water is that the gas may escape and thus enable all the plaster in the roll to be evenly moistened. If laid on the side, the moisture will only extend to some parts, leaving others dry and unfit for use.

The patient being suspended, the jacket is applied by the surgeon, standing or sitting at the back of the patient, while an assistant sits in front, steadying the patient by his knees and rubbing and smoothing the bandages which are being applied.

Begin at the waist, taking one or two turns around the smallest part of the body, and then going down in a spiral form, each layer overlapping the other half or two thirds of the width of the bandage until reaching the trochanter; then, having taken one or two turns around the pelvis, reverse the bandage, and gradually proceed in the same spiral manner upward until you have covered the entire body to the top of the sternum.

This process is repeated till there are a sufficient number of thicknesses to support the body, the number of bandages to accomplish this object, of course, depending on the size of the patient.

In cases where the disease is in the lower dorsal or lumbar vertebrae this is all that is required. If the disease is at the mid-dorsal or cervical vertebrae, it then becomes
necessary to add the jury-mast to the jacket in order to take off the weight of the head from the vertebral column.

In many instances great advantage is derived from the addition of Whitman's shoulder brace to keep the chest well expanded, and press the shoulders back into the jacket.

In the great majority of cases the jacket can be applied while the patient is suspended vertically, with the greatest ease to himself and the surgeon; but in exceptional cases, where there is paralysis, where the heart is too weak to allow the patient to remain upright for any length of time, or in cases of excessively fat and feeble people, Davy's hammock, with holes cut to allow projection of the head and feet, is to be preferred; traction being made at both ends of the body to the point of comfort while the jacket is being applied.

Now, to pass to the subject of lateral curvature of the spine, a deformity which has nothing in common with spondylitis, except that they both affect the spine—and I might say in passing that, surprising as it may seem, there appears to be in the mind of the profession at large very often a lazy mingling of these two troubles, which bear about the same relation to each other as tumor albus and genu valgum, and, although I have written repeatedly and at length on the different modes of employing plaster of Paris in the treatment of these two affections, it seems to me, from the papers I read in the various medical journals, that a number of physicians are still under the erroneous impression that I use gymnastic exercises in cases of Pott's disease, and employ immovable plaster jackets in cases of lateral curvature. In the treatment of lateral curvature the position that I hold is, that a large number of cases if seen early may best be treated by improvement of the general tone of the system, increasing muscular strength, and educating the muscular sense of the patient to the correct carriage of the body without the aid of any mechanical support whatever. In other cases it is not sufficient to rely upon the patient alone, but recourse must be had to artificial support to hold the trunk in a correct position until the patient is capable of voluntarily maintaining it so; and in a third class, where marked deformity is present, oftentimes accompanied by great pain and disability, artificial aid is often necessary to support the body in an improved position during the entire life. One of the most useful means, in my experience, of rectifying lateral curvature of the spine has been vertical, partial self suspension accompanied by manipulation, and with me nothing has been so serviceable in holding this improved position as a corset made of flexible material applied to the body in its improved position, which, then hardening, retains this improved shape; and of the various plastic materials that I have tried, plaster of Paris has answered my purpose better than anything else. I wish to raise my voice in emphatic protest against what many gentlemen seem to regard as my method of treatment in lateral curvature—namely, placing the patient in a plaster jacket and leaving her there for a number of months, then removing the jacket and replacing it by a second. The plaster corset is simply for the purpose of holding such improvement in position as you have been able to obtain by your manipulations, and does not in any way improve the shape of the patient beyond this, and should be renewed as often as improvement in the form justifies, and worn only so long as the patient is unable voluntarily to maintain an equally good position without its aid; and during the treatment it is essential that the corset be removed while the patient exercises daily for the purpose of gaining that increased physical health and muscular tone which are necessary to the successful treatment of lateral curvature of the spine.

In applying plaster of Paris bandages in cases of lateral curvature, a shirt of double length is used, pads are placed over the mammae, and a strip of tin two inches wide is placed next the skin from the sternum to the pubes, on which to cut off the plaster; and, instead of being suspended by the head and axilla, the patient suspends herself by pulling on the free end of the rope which passes from the head-swing over the pulley, while she keeps the arms outstretched, the upper hand being on the concave side. As soon as the plaster is set, which should be the case by the time the corset is finished, it is split open down the front and removed while the patient is still suspended. A thin slice is then taken from each edge of the shirt and the corset held together by a roller bandage and dried. When dry, the next day, it is put on the patient while again self suspended, and fastened by a roller bandage; then trimmed out under the arms and above the thighs until comfortable, and removed. The extra length of shirt is then reversed over the jacket and sewed to itself, covering in all the plaster, and lacings are sewed on in front.

Without wearying you further by speaking of my own ideas on these two subjects, I would pass to the opinions of others, as any treatment which will not stand the test of time and critics is not worthy of acceptance.

While the first demonstrations of this method of treating Pott's disease and lateral curvature were received with marked enthusiasm in all parts of the world, wherever the demonstrations were made, it remains to be seen whether, after the lapse of twenty years, the same enthusiastic approval will be accorded to it, and I accordingly have written the following letter to some hundred of the most distinguished orthopedic surgeons in various parts of the world:

285 FIFTH AVENUE, NEW YORK, November 19, 1894.

Dear Sir: I have been invited to read a paper before the New York Academy of Medicine on January 3, 1895, on The History of the Treatment of Spondylitis and Scoliosis by Partial Suspension and Retention by Plaster of Paris Bandages—setting forth the present status of this form of treatment before the medical profession of the world after twenty years of experience.

Will you kindly let me have, at your earliest convenience, your views on this subject, whether for or against the plan of treatment, together with such other suggestions as you may choose to make, in order that I may embody them in my report.

Trusting that I may have the pleasure of an early reply, I am,

Yours very truly,

LEWIS A. SAYRE, M. D.

I have received answers from a large number of them, and have embodied extracts from them in this report. Those that are opposed to it I will read entire; of those in favor I will use only extracts.
Robert Jones, Liverpool, said: "I am not favorable to suspension in the treatment of lateral curvature, and would trust entirely to exercises, muscle-heating, and, where necessary, elevation of the heel of the boot."

E. Muirhead Little, London, says: "In re gypsum jackets, I have not used one for many years. I prefer pork-plastic, felt, or steel supports."

Bernard Roth, London: "I have treated with much success upward of two thousand cases of scoliosis, including many of extreme deformity, by my method of posture and exercise, without any mechanical support whatever, and I have never found suspension of any use in scoliosis."

In reference to spinal cases, for the first ten years of my practice as an orthopedic surgeon I applied your plaster-of-Paris bandages almost exclusively with varying success, but for the last ten years I have discarded them altogether in favor of the late H. O. Thomas's spinal splint with axillo-scapular straps. I have modified this splint, so that the patient's back can be uncovered for examination and the instrument replaced and re-fixed while the patient is lying prone the whole time.

Noble Smith, London: "Probably the most fallacious form of treatment is that of applying plaster-of-Paris jackets. Among the many enthusiastic surgeons who at first made use of them, there are very few having had much experience who have not now given them up as a failure. Plaster-of-Paris jackets ought to be utterly condemned, because, first, of their great weight; second, their interference with free respiration and cleanliness; and third, the fact that they act simply as heavy, unscientific corsets, pressing upon the chest, and add very little to the support of the spine."

B. E. McKenzie, Toronto: "With the exact manner of treatment referred to I have had but little experience. For several years I have employed some form of gymnastic treatment associated with the employment of forceful correction through suspension, with lateral traction, manipulation of the spine, etc. The objection which presents itself to me in the use of any re-tentive appliance is that it tends to atrophy and to produce weakness of the trunk instead of aiding in the development and strengthening of the parts."

H. Hodge, of St. Louis, does not think he has ever seen a very good result in scoliosis from the use of the jacket, and prefers the steel assistant.

John Kildon, Chicago: "I have used the permanent plaster-of-Paris jacket in spondylitis from time to time during the last twelve years, applied as you directed, with the patient partially suspended, when I have been unable for any reason to obtain an antero-posterior steel spine brace of the Taylor pattern. I have also used the plaster jacket in certain cases of spondylitis where the lateral deformity was so great that the steel brace could not be satisfactorily adjusted. In all those cases where the jacket has been used for the posterior curvature simply I have not been able to prevent an increase of the deformity, and in all those cases that have come under my observation after having been treated by other surgeons I have been given a history of steadily progressive increase of the deformity. In those cases, however, where there has been marked lateral deformity I have found the deformity progressively diminish under treatment by the plaster jacket; but in these cases I have not continued the treatment with the jacket after the lateral deformity had disappeared and with the posterior curvature increased to any considerable extent."

In scoliosis it has been my custom for the past two or three years to use the lacel plaster jacket in all cases except the very slight ones. I use it in connection with partial suspension and pressure by the squeezing machine, and I am satisfied that I have obtained a much greater degree of correction of the deformity than I had become accustomed to obtain either with exercises alone, after Roth's method, or with the use of the leverage lateral brace formerly applied, and perhaps still used, by Dr. Shaffer of your city. Under treatment by Dr. Shaffer's brace I used to find nearly all my cases grow somewhat more deformed. None of them made any material gain, although treated for long periods. Under the exercise treatment of Roth very slight cases at times fully recovered; moderately severe cases gained somewhat, and rarely ever grew worse; in severe cases the deformity did not in any way diminish, and some few did not appear to receive any benefit whatever. At this time I am satisfied that the plaster corset used in connection with the squeezing machine and exercises gives in my hands the best result in the treatment of scoliosis."

James K. Young, Philadelphia: "In answer to your favor of November 28th, asking for my views upon 'The Treatment of Spondylitis and Scoliosis by Partial Suspension and Retention by Plaster-of-Paris Bandages,' I can best answer by quoting from my recent work, Treatise on Orthopaedic Surgery, 1894, under the treatment of these two subjects:"

Spondylitis.—After describing the technique now employed, I say: "While possessing certain advantages of economy, requiring less special experience in its application, and being entirely beyond the control of the patient or attendants, there are certain positive disadvantages—the encroaching of the body within a solid support, the inability to inspect the condition of the skin and note the progress of the affection, the formation of excoriations, ulcerations, and abscesses without the knowledge of the surgeon, the lack of cleanliness, etc.—which relegate it and its modifications to a secondary position. When split, form-fitted with linings, and applied and removed at will, it loses part of its efficiency, but there is a gain in comfort and cleanliness. It is of decided value, however, for patients who are unable to bear the expense of even the cheapest apparatus; in such cases, with attention to detail, a cure may often be effected, and the writer has in public practice frequently proved this statement, especially when the disease was located in the lumbar region."

"In justice to this mode of treatment it must be added that there are certain cases in which it is the best and most efficient; this applies particularly to the lateral deviation of the spinal column present in certain cases of Pott's disease and in lower lumbar disease. It is, moreover, important that the surgeon be familiar with both the plaster-of-Paris jacket and the spine brace, adapting each to the special requirements of the individual case. Individual experience leads me to employ the steel spine brace wherever it can be carefully adjusted at short intervals under personal supervision."

Scoliosis.—I believe in and employ partial suspension, but do not now employ plaster-of-Paris jackets in the treatment of scoliosis. I prefer to treat these cases early by mild, long-continued movements, exercises, posture, and massage—methods by which I have achieved the greatest success."

Thomas G. Morton, Philadelphia: "In private practice I do not use the plaster apparatus you refer to, but at the Orthopaedic Hospital we now and then resort to it when the patient is unable to procure the Lenz spinal apparatus which we commonly use."

Joel E. Goldthwait, Boston: "I would say that for routine treatment I use a form of back brace, practically the Taylor, reserving the suspens-ion and jackets (plaster) for those cases which the brace fails to hold, or in which there is lateral deformity."

In these cases, if ambulatory treatment is desired, I think the jacket is by all odds the best form of treatment."

CharesL. Soudler, Boston: "I have nothing novel or new
to the common experience of surgeons with this form of retentive apparatus. I would say simply that in cases of

I was inclined to use more and more the hammock as a means of extension rather than the tripod and sling.'

Robert W. Lovett, Boston: "I have used in the treatment of lateral curvature the plaster jacket, I think in all its forms, and with certain modifications I still continue to use it. Believing as do very firmly in gymnastic treatment as an essential part of the treatment, I have abandoned the use of the fixed jacket except in unusual cases, where I apply it to a patient who is forcibly corrected, leaving it on only for a short time. This measure I have found of use in some of the very severe cases. It is applied under suspension.

"A method which I have used extensively has been to apply a jacket to the patient while suspended, cut the jacket off down the front, and fill it with plaster, thus obtaining a cast of the body; then, by the method described by Dr. Bartow, of Buffalo, I remove the prominence on the convex side of the cast, building it up on the opposite side; in some cases overcorrecting the deformity, in other cases bringing them nearly to the straight line. To this cast I apply a jacket over an under vest, cutting it down the front and having it provided with fastings. This I have been accustomed to use in connection with gymnastics and forcible correction. It represents the patient's condition as it would be if a decided improvement had taken place, of course. I am a believer in the efficiency of this "corrected" jacket.

"I have also used braces to accomplish the same purpose. I cannot account myself an advocate of the jacket to the exclusion of the brace, and I use sometimes one and sometimes the other. In milder cases I depend for the most part on gymnastic treatment. I trust I have answered your inquiries."

133 Newbury Street, Boston, December 19, 1894.

My dear Dr. Sayre: In reply to your communication, let me say that I find the treatment of Pott's disease by partial suspension and retention by plaster-of-Paris bandages in a large number of cases of curvature of the spine to be most beneficial. It is particularly adaptable for cases below the seventh dorsal. In the convalescent stage I use removable jackets—either plaster, leather, paper, or aluminum removable corsets—where these are within the means of the patient. In a number of cases, however, I make use of braces. These are largely in the cases that are in the upper portion of the spine and where careful nursing can be given. In such cases, where thorough nursing can be given, I am in the habit of making an antero-posterior support. In certain acute cases a fixed plaster jacket seems to give a more thorough support than the brace as ordinarily applied. It has seemed to me that an antero-posterior support could be made to hold as well as a plaster jacket even in the portion of the spine to which the plaster jackets are most suitable, but practically, in the majority of cases of the acute sort, certainly in poorer practice, a plaster jacket will be found the readiest and most efficient. In lateral curvature I am also using plaster-of-Paris jackets with partial suspension, but I have combined with it also a later traction and direct pressure. Here, again, I am in the habit of using substitutes for plaster jackets—namely, leather, paper, and aluminum.

With sincere regards, E. H. Bradford.

Henry O. Marey, Boston: "I thank you for calling my attention to the paper which you have in preparation. I am sure that I can add very little of value upon the subject, since from the first I have considered you my master, and take pleasure in writing you the reasons which caused me to first seek your acquaintance. The first article which you published upon the treatment of angular curvature of the spine by means of suspension and the application of the plaster jacket impressed me so favorably that after its careful study I went to New York for the sole purpose of seeking your instruction, and, thanks to your courtesy, I did not return until I had familiarized myself with every detail.

"It is very probable that I was the more favorably impressed with your method, since for some years I had used plaster bandages for almost every variety of fracture. .... Another case which I cited, of a woman confined to the bed because of a dorsal curve, at once commended her work after the application of the jacket, at which time she was three months pregnant. She refused to part with her jacket or have it replaced by another, chipping away in front as the enlarging abdomen demanded, until her labor commenced. No other jacket was applied, and somewhat recently I had the good fortune of examining her, all these years the resulting cure having remained complete with only a slight deformity. As you are well aware, procedures emanating from any other source have been accepted by the Boston profession only after repeated proofs of real merit. To this conservatism your teaching proved no exception. I was not alone the first to introduce plastic splints to the profession of Boston, but also your methods of the application of the plastic jacket, and unceasingly wrote and talked upon the subject. Much excellent work has been done here for a good many years, especially at the Children's Hospital, but unfortunately the general profession are still wanting in technique and training. I enclose you a reprint of 1877 upon Plastic Splints in Surgery, and call your attention to its closing sentences. What I then said I now repeat, but more than all as the outcome of your teaching upon this subject do I prize a personal friendship."

ALBANY, N. Y., December 14, 1894.

Lewis A. Sayre, M. D., New York City:

My dear Doctor: In reply to your letter of November 19th, I am reminded largely of the early history of your work in the treatment of spondylitis and scoliosis when first presenting the subject to the attention of the New York State Medical Society. You will remember that I was the first who presented a case—that of Miss M.—for your treatment, application of the bandages, etc., and the result was quite decidedly satisfactory. While for the past five years my line of practice has been away from orthopedic surgery, yet my impressions, in answer to your questions, would be that my results in the treatment of angular curvatures of the spine have been decidedly satisfactory. In the treatment of lateral curvature I can not speak so emphatically. For angular curvature I applied the first plaster-of-Paris dressing put on in this city, after having read a report of one of your clinical lectures at Bellevue Hospital upon the subject. I applied the bandages directly to the surface of the body, and had the pleasure of seeing the little patient do remarkably well.

Hoping these few stray notes will be of service to you, and that you will pardon my delay in answering, believe me,

Sincerely yours, A. Vander Veer.

Lewis Balch, Albany: "I have not applied a plaster jacket for six or eight years. From the time you put on one before the State Medical Society, in the winter of 1878—I think that was the date—up to 1886, I used the jacket for all cases of spinal curvature coming under my charge. In general I can say the treatment was successful, but I noticed in some cases of rotary lateral curvature the patient seemed to slip down through the jacket, no matter how carefully it was applied, and
the treatment failed. Eventually I had better success in ante-
or-posterior curvature than in the other.

"I know the jackets were properly applied, for you taught me how to put them on both here and in your own office."

M. H. Burton, Troy: "I have used the Sayre jacket in treating cases of spondylitis and scoliosis in the Troy Hospital and in private practice with decided and manifest success. I have witnessed its use in Marshall's Infirmary, Troy, N. Y., and the results were not gratifying. I have seen cases also which had been treated by yourself, and found complete recovery the result. It would not be within my province to suggest to you in regard to the Sayre jacket or the counterpart appliances.

"Your experience and knowledge in the matter preclude such suggestions, if I had any to make—which I have not. As compared with other jackets or appliances, I find no single point in their favor, so far as experience and observation give me knowledge.

"In all respects I find the Sayre plaster-of-Paris appliances or jackets the most efficacious, convenient, and valuable, and the ones causing the greatest success in the treatment of the diseases for which we apply them."

R. B. Bontecou, Troy: "Your letter of November 19th was duly received, and I have nothing more to state than what the profession at large have stated and will state in admiration of your device to accomplish physical rest by fixation, which I believe is the great principle to observe in the treatment of disease of the spinal column and the greater joints. I have relieved and cured a multitude of suffering humanity by your method, both in hospital and private practice—adults as well as children. Of late years I have substituted water glass of heavy specific gravity for the plaster, finding it equally resistant and durable, and lighter, and can be cut open when necessary and used as a corset more readily than plaster.

"I have also, in children with posterior spinal deformity, often substituted the prone position in a hammock of cotton flannel, with advantage, utilizing the ham-mock as one of the envelopes. It is certainly more comfortable for children than the vertical position."

Ansel G. Cook, Hartford: "About eighty per cent. of my cases of spondylitis wear solid plaster-of-Paris jackets, with or without the jury-mast; about fifteen per cent., plaster or leather corsets made to lace in the front; and about five per cent., for various reasons (position of abscesses, imperfect development of hips, complications of other joints, etc.), wear various forms of braces. This does not include the very severe cases that are confined on wire or plaster and board curasses, or a class of cured or convalescent adults whose backs are not strong and who require some support. These do best, I find, with a light back brace, padded the whole length of the brace, worn under an ordinary pair of corsets.

"The mild cases of scoliosis I treat with exercises alone; the more severe, with exercises supplemented with braces that do not hold, but compel the patient to hold himself in a corrected position (you will note the distine ion); and the most severe, with plaster-of-Paris or leather corsets. I hope your paper will touch on the subject of suspension, forcible correction and retention, which has so many enthusiastic advocates at present.

"A great deal of trouble, I think, arises from improperly made and badly fitting jackets; it certainly requires considerable practice to make a good one, and when a man condemns plaster jackets you are inclined to agree with him when you see the thing he has made and calls a jacket. On the other hand, the man who sends his patient to an instrument-maker to have a brace fitted, without giving accurate directions as to how the brace shall be made, and attending personally to the fitting of it, is not likely to get any satisfactory result."

Dr. Lewis A. Sayre: Buffalo, December 5, 1894.

MY DEAR DOCTOR: In reply to your favor of November 19th, asking my views in the matter of the treatment of spondylitis and scoliosis by plaster-of-Paris bandages, I would say as follows: First of all, I would wish to acknowledge the benefits which I, like all other surgeons, have received from the views upon treatment which you have published so widely and with which your name is so inseparably connected.

So far as the treatment of acute spondylitis is concerned, and at that time when absolute fixation is so absolutely necessary, I must say that I know of nothing that can take the place of a plaster-of-Paris corset. With regard to the later treatment at a time when plaster has become irksome, or when the acute stage is past and the patient's personal comfort can be more consulted, I must say that, for my own part, I think that other mechanical devices can be substituted which permit of sufficiently frequent removal to keep the patient more comfortable. I do think that braces or jackets of various kinds can be devised that give sufficiently complete fixation to meet the indications, and that are much more agreeable for the patient. But, in the early and very acute stages, and in a certain class of hospital and dispensary patients, I think that plaster or its equivalent, yet to be discovered, more completely fills the indications than anything else.

With regard to scoliosis, it is not my own personal custom to resort much to plaster jackets, except as I may put one on in order to obtain a cast of the body around which to construct a suitable brace. I think these cases are more often injured by too long rest of the muscles, and for all except the invertebrate cases I much prefer a movable corset which will permit massage or very much more active muscular training. The more I study and have to do with lateral curvature, especially in the young and growing, the more I believe in the expediency of gymnastic treatment, and the less absolute reliance I like to place upon support. I may sum it all up by saying that in my estimation a happy combination of the two constitutes the best treatment.

I appreciate your request for my own views, which I advance with no little hesitation to such an authority as yourself, and am, very sincerely yours,

BOWELL PARK.

KANSAS CITY, Mo., December 4, 1894.

Dr. Lewis A. Sayre, 285 Fifth Avenue, New York:

MY DEAR DOCTOR: Yours of the 19th just to hand, and I would say in reply that in spondylitis the upper dorsal and cervical region I have used with good results and advocate recumbency. Where the disease is manifest below this part, I use suspension and retention by plaster of Paris bandages—fixed dressing if the trouble is active, and movable apparatus or laced plaster-of-Pans dressing if angular curvature has taken place.

In scoliosis I find the suspension and retention by the plaster-of-Paris bandages, cutting down and lacing, my best method.

Your friend,

J. D. GRIFFITH.

MINNEAPOLIS, December 3, 1894.

DEAR DR. SAYRE: In reply to your kind letter, would say in the majority of cases of spondylitis I use partial suspension and retention by plaster of Paris, and when I do use a steel support it is usually to cater to the prejudice of my patient, for since I have known how to apply the jacket properly I have been able to do more good to a greater number with it than with any other means at my command.

For the past two years in treating scoliosis I have abandoned braces and supports of every kind, and I believe with advantage to my patients, except in cases in which the deformity is increasing very fast, and then I apply a plaster jacket.
until I have had time to build my patient up and get her able to stand alone as it were. Fraternally, J. E. MOORE.

Hunter McGuire, Richmond, Va.: "Your letter of November 19th has been received. In the treatment of spondylitis nothing, in my opinion, is better than partial suspension and retention by plaster-of-Paris bandages. Having a son with this disease, there is nothing in medical literature on this subject that I have not studied. I have practiced several other devices, but have never found anything equal to the plaster-of-Paris bandages. When I use them in scoliosis, however, I always arrange them so they can be removed, and endeavor to strengthen the muscles by massage, electricity, and gymnastics."

116 South Eighteenth Street, Philadelphia, November 28, 1894.

My dear Dr. Sayre: In all cases of spondylitis in the early stages, where the patient is not confined to bed, I use plaster-of-Paris bandages, as suggested by you. Later, in private practice, I use some form of steel supporting apparatus. In my hospital work and among the poor I usually employ plaster-of-Paris jackets from the beginning to the end of the treatment of the case, and at all times when the cost must be considered.

In scoliosis I use the plaster-of-Paris jacket, which is applied at short intervals, to support the spine and overcome the deformity, believing that we can accomplish better results in this way than by more expensive and cumbersome apparatus.

When the curvature has been overcome I apply some form of light supporting apparatus. Of course in scoliosis I do not neglect to use stretching and pressure, with gymnastic exercises, to increase the flexibility of the spine.

I shall be glad to give you more details if this short account is not sufficient. Believe me, very truly yours,

William J. Taylor, M. D.

November 28, 1894.

Dr. Lewis A. Sayre, 295 Fifth Avenue, New York:

Dear Dr. Sayre: In reply to your note of the 19th I would most gladly say that the profession owes much to you for developing the use of plaster of Paris as a surgical dressing in a great variety of cases and conditions. In regard to its use in spondylitis, it has been a Godsend to hundreds of poor people who would otherwise have been without this most economical and effective method of fixing the spinal column until repair takes place. I know of no method so convenient for producing absolute fixation of the bones of the spinal column. It certainly has its disadvantages; but your work in this line has stimulated efforts at substitution which have obviated its disagreeable features. The great principle underlying the treatment, however, that of rest and fixation, has steadily and persistently taken firm hold upon the profession at large. While method and means may change, the principle will live.

In regard to self-suspension for scoliosis, it is one of the helpful means of rectification, and I value it highly. I am opposed to apparatus for scoliosis, both on the theoretical and practical grounds, whenever it can be avoided. I believe in strengthening the muscular power by active and passive gymnastic movements, as I consider them the essential elements in effecting a cure. At the same time I do not deny that there are cases rapidly growing worse which require permanent support.

When plaster of Paris is used in these cases it should, in my judgment, be employed as a corrective agency, with constantly increasing pressure upon the projecting portions of the body, as advocated by yourself and by the plan of Dartow. Thanking you again for the earnestness with which you have pursued this branch of surgical work, I am

Yours very sincerely,

De Forest Willard.

John Cluverus De Costa, Philadelphia: "The custom in the Philadelphia institutions with which I am connected is to treat acute and early spondylitis by means of rest in bed, and to rely entirely upon a plaster of Paris, applied during suspension by your method, for the completion of all cases and the cure of patients."

1611 Spruce Street, Philadelphia, November 30, 1894.

My dear Dr. Sayre: I am in receipt of your letter of November 19th. I am very strongly in favor of the plan of treatment by plaster of Paris, applied during partial suspension, in cases of spondylitis below the mid-dorsal region, also as a means of holding a jury-mast in cases above mid-dorsal region. I am strongly opposed to the use of plaster of Paris applied in any position for scoliosis where it is allowed to remain for more than one week's time, because it tends to increase the muscular atrophy from dis-use. I believe that it would interfere with the object of your paper if I do more than briefly state my views as above. I can but believe that the mechanical advantages of plaster of Paris have been seriously interfered with by the injudicious employment of it in unsuitable cases and in an unmechanical manner. It has often appeared to me that plaster of Paris was applied apparently with the idea that it acted as a therapeutic measure by absorption in some such way as many of the nostrums are supposed to act. It is only in this way that I have been able to explain the irrational manner of its application. I remember saying in one of my clinical lectures that it seemed a great misfortune that Professor L. A. Sayre could not communicate his skill in selecting the cases suitable for the method as well as his skill in applying plaster of Paris, to prevent the terrible abuse to which it has been subjected.

Yours most sincerely,

H. AUGUSTIN WILSON.

B. Morrill Eckett, Cincinnati: "In reply to your request for my opinion concerning the treatment of spondylitis and scoliosis by partial suspension and retention by plaster-of-Paris bandages, I will say that this method is, I believe, the best thus far presented when applied with skillful hands."

"Its advantages. Disadvantages.
1. Non-custody. 1. Uncleanliness.
2. Perfect adjustment. 2. Excessive weight.
3. Inexpensiveness. 3. Liability to fracture.
5. Rapidity. 5. Frequent reappliation.

To overcome the disadvantages, I have, as a rule, used the leather jacket supported by steel made from the original plaster cast. The leather jacket does not meet as many requirements as the plaster, but, until some of the disadvantages of the plaster are overcome, I believe it will be necessary to use the leather, believing that it excels the other substances, such as metal, wood, paper in any form, or any of the various apparatuses."

Edmund Andrews, Chicago: "The plan is a valuable one in many varieties of cases. One of the important advantages in the West is that family physicians in distant mountain and prairie regions, far away from instrument-makers, can always make use of it."

Another advantage is that by its use the remote physician protects his patient from getting useless and injurious braces made by city instrument houses from inadequate measurements sent by mail.

The practical difficulty as to its use by distant country practitioners is the tendency of some of them to leave it on without change so long that the skin becomes foul and offensive, and their neglect to guard the prominences of bone, thus producing ulcers by the pressure."
As the patient may be ten or fifteen miles distant over bad roads, they think they can not go to him very often.

It is a serious question for a far-off country doctor as to what he can do for a distant spinal case having scanty pecuniary means. My extensive correspondence with these people has impressed me strongly with their difficulties. I use the plaster jacket frequently, but in many other cases I prefer apparatus of other material."

W. R. Whitehead, Denver: "I recently received your letter about spondylitis, and hasten to reply at my earliest convenience. I wish that I could add something really valuable and interesting to what I have already expressed concerning your treatment of this disease. I am sure, my dear doctor, that no one appreciates your efforts in this matter better than those who have profited, as I have, by your instruction in the application of this the most valuable means of treatment, in my opinion, of Pott's disease of the spine, which is one of the most troublesome surgical affections with which we have to contend.

I am opposed to all stiff braces as inefficient, painful to the patient, and often a most useless expense. The trouble is, generally, that the Sayre jacket is not properly applied; it is almost always, in my experience, too heavy, or the plaster is of poor quality; sometimes the plano-felt pieces about the hips are omitted, or there is something about the jacket that shows inefficiency in its application, or a want of proper knowledge of or proper appreciation of the purposes for which it is applied, as simple as they are. These things are not the fault of the Sayre jacket, but the fault of those who sometimes attempt to avail themselves of this excellent device—indeed, the fault of the medieus imparates with which this country is abundantly supplied. Take, for example, an intelligent country doctor, far removed from all the conveniences of a city, and if he understands how to apply your jacket properly, and has any ingenuity at all and a little good plaster of Paris, he can, in my humble opinion, make for his patient a better and more comfortable and more useful appliance for the treatment of spondylitis than all the nickel-plated steel braces and other spinal 'contraptions' offered for sale and advocated by instrument-makers and recommended by their inventors."

"P. S.—Some doctors, it seems, are invited to send cast a mold of the bust in plaster, and a jacket will be furnished after such a mold. My comments are that a doctor who has not experience and sense enough to make a suitable jacket can not make a good mold."

*(To be concluded.)*

**COMPLICATED HERNIAE.**

**By SAMUEL E. MILLIKEN, M. D.,**

**ATTENDING SURGEON TO THE RANDALL'S ISLAND HOSPITALS.**

While strangulation is the gravest complication which takes place in hernia, it is of the less alarming but very important ones with which I shall deal—viz., adhesion, undescended, uncircumcised, and hydrocele of the cord.

Adherent hernia, in my opinion, much more frequent than is generally supposed, as very limited attention is paid to the mechanical treatment of this class of surgery by the general practitioner, but is left to the care of instrument makers or the patient himself. Another reason for the non-detection of such a condition is the absence of any acute symptoms, as only in rare instances does anything else than omentum become adherent. This, however, is very frequent and should be detected early.

It may seem a strong assertion, but I am convinced that this unfortunate state of affairs is often brought about by the application of a truss without having fully reduced the hernia, thus rather encouraging the adhesion. When the hernia is intestinal there is little danger of such a mistake, unless it be the omentum, as the pain induced will cause the patient to remove the apparatus. One case which came under my observation, that of a child less than two years of age, on whom I refused to apply a truss, subsequently went to one of the large instrument houses of New York and was fitted with one. On the operating table it was found that the greater part of the omentum was adherent, which no doubt was made worse by the truss. Had any other part of the intestinal tract been subjected to such pressure, strangulation would no doubt have occurred.

The following case illustrates the endurance of omentum to truss pressure without strangulation:

Mr. U., aged forty five years, hotel clerk, came to me April 18, 1892, giving a history of having worn a same side truss for five years, but the hernia had never been retained for more than a week at any time. On examination, with the patient in the upright position, there protruded a left oblique inguinal hernia half the size of the fist. It was largely intestinal, and when he assumed the recumbent posture all could be reduced except a piece of omentum about the size of the end of the thumb. By considerable pressure even the omentum could be forced into the inguinal canal, but it would immediately reappear when the hand was taken off. The adhesion of the omentum to the sac could be demonstrated by first reducing it into the canal and retaining it there with one hand, while traction was made on the cord with the other, which caused the hernia to reappear. Although the condition was explained to the patient and operation advised, he declined to undergo the same.

A "complete band truss with shank" (see New York Medical Journal, November 7, 1889), such as I presented to the New York State Medical Association, September, 1889, was applied with the hope of retaining the intestinal part of the hernia without attempting to hold the adherent omentum. The patient has now been under observation for over two years and, although he is very stout, the truss has been worn with comfort and no further changes have taken place in the adherent omentum.

The following case, referred to me by Dr. L. C. Jones, of this city, illustrates how small an omental adhesion may exist and yet greatly interfere with the mechanical treatment:

Mr. J., aged twenty-six years, came to me October 19, 1894, giving a history of hernia during childhood, but he had not worn a truss until a few weeks before I saw him. During the past summer he went before the New York City Civil Service Board, when he was rejected for hernia.

Mechanical treatment proving unsatisfactory, he decided to try the "radical cure." On examination, the right side of the scrotum was found to be about a third larger than the left, and the cord structures, as they passed over the rami of the pubis, were three times the size of the unaffected side. The appreciably nodular character of the scrotal contents led me to diagnos-
titerate an omental hernia. With the patient prone the hernia was reduced, but with difficulty, and the testis was at the same time drawn up almost to the external ring. By making traction on the cord the hernia could be reproduced.

It being clear that an adhesion existed, I operated October 24th, and found only one small fragment of omentum grown fast to the most dependent part of the sac. This was tied off with catgut and the rest of the omentum returned to the abdomen. Another complication in this case which was met with was a very narrow constriction of the sac at the site of the internal ring, which was divided before attempting to reduce the omentum and accounted for the force which was required to accomplish partial reduction before the operation.

This marked fibrous constriction was met once before in a case of adherent omental hernia which had become complicated by strangulation of a loop of small intestine. In both of these cases the reconstruction of the canal was performed after the method of Bassini, which gives the surgeon abundant opportunity of inspecting the condition of the internal ring before opening the sac or attempting to return the hernial contents.

Undescended testis, while not so common as adherent omentum, rarely exists long without being followed by hernia. The mechanical treatment is rarely satisfactory unless the testis has descended below the external abdominal ring. When in the canal, the pressure required to retain the hernia will often not only produce great pain but prevent the natural descent of the organ.

I have operated on two cases with this complication by dividing the adhesions to the cord structures well up to the internal ring, so as to allow the testis being brought down and then anchored to the scrotum by catgut sutures through the tunica vaginalis. The canal was built up after the method of Bassini. By making the external ring small the testis can not get back into the canal, and it will soon adapt itself to the new position.

Encysted Hydrocele of the Cord.—Hydrocele of the cord is more frequently mistaken for hernia than any other condition. It does occasionally occur simultaneously with hernia, and when so should be recognized and differentiated. When small it can be reduced into the canal, but by traction on the cord the characteristic, uniform cyst can be reproduced. The freedom from pain and the firmness of the swelling should cause it to be easily distinguished from hernia. Aspiration and the injection with a few drops of carbolic acid will usually accomplish a cure, and then the treatment of the hernia can be carried out.

Conclusions.—1. Besides becoming strangulated, hernia may be complicated by adhesions, undescended testis, and hydrocele of the cord.
2. Omentum often becomes adherent without causing any alarming symptoms, and is the greatest obstacle in the way of successful mechanical treatment.
3. The sac may take on adhesions under an ill-fitting truss and yet not become strangulated.
4. Undescended testis rarely exists alone and is usually complicated with hernia.
5. Encysted hydrocele of the cord, while often mistaken for hernia, may be only a complication.

March 16, 1895.]

LEADING ARTICLES.

NEW YORK MEDICAL JOURNAL, A Weekly Review of Medicine. Published by D. APPLETON & CO. Edited by FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, MARCH 16, 1895.

THE INDUCTION OF "ASEPTIC CELLULITIS" AS A THERAPEUTIC MEASURE.

We have received, presumably from the author, Mr. E. Hurry Fenwick, of London, a reprint of a noteworthy article that appeared in the January number of the Clinical Journal, entitled A Clinical Lecture on the Value of Exciting Aseptic Cellulitis in the Treatment of Obstinate Inflammatory Affections of the Urinary Organs. Mr. Fenwick believes that there are many chronic or obstinate inflammatory conditions of the solid viscera which may be materially benefited by cutting out to them through the parietes of the body, by exciting "suppuration of a benign type in the cellular tissue of their immediate neighborhood," and by draining off the products of inflammation through the vessels of this layer. He has been accustomed to term this method of dealing with chronic visceral inflammation "aseptic counter-irritation," and he thinks it is nothing more or less than a more accurate and more energetic method of applying the seton, blister, or iodine paint of old-fashioned medicine. He submits that the surgery of the present day can advantageously substitute for such surface applications the more powerful and effective counter-irritation of an inflamed and drained cellular tissue.

Mr. Fenwick's attention was first drawn to the matter, he says, in 1887, when he was suddenly called upon to treat a patient supposed to be suffering from rupture of the bladder. He had much dullness above the pubes, though the bladder was empty, and a great swelling was detected in the recto-vesical pouch. On laying open the cavity of Retzius by a suprapubic incision, Mr. Fenwick found the trouble merely an acute interstitial or parenchymatous cystitis which subsequently proved to be due to Bilharzian disease. In a few days the enormous swelling which had previously existed in the neighborhood of the bladder disappeared, and it struck Mr. Fenwick that this unlooked-for result was probably due to drainage of the inflammatory products through the suprapubic incision. Since then he has gradually collected some pathological as well as clinical material which convinces him that inflamed cellular tissue exercises a considerable detergent effect upon any solid viscus with which it is in contact, and that these powers have either been overlooked or not thoroughly appreciated by the profession.

The pathological effects of suppuration or extravasation of blood into the cellular tissue in the neighborhood of solid viscera upon the health of the organ are, he says, well exemplified in the kidney. The effects of large collections of pus or of blood upon the plumpness of the kidney can be demonstrated either on operation or post mortem, he adds.
Mr. Fenwick gives notes of a case in which an enormous subperitoneal haemorrhage around the kidney produced atrophy of that organ, and mentions various other cases showing the beneficial effects of incision and drainage of the cellular tissue in the immediate neighborhood of the kidney, the bladder, or the prostate. He adds that he has encountered equally satisfactory cases in general surgery, especially in the surgery of the liver. He suggests that in obstinate inflammatory conditions of the urinary organs of a subacute type, which have resisted ordinary methods of treatment, an incision be made over the offending vesica, the cellular tissue in its immediate neighborhood freely opened with a carefully aseptized finger, and the wound subsequently drained for a week or a fortnight.

While there is practically no danger attendant upon such a procedure properly carried out, it is difficult, as Mr. Fenwick says, to conceive anything more detrimental than a cellulitis set up by a slovenly, septic surgeon; and it is not easy, he adds, to realize the damage which may be caused by a surgeon "breaking into a tubercular or carcinomatosus deposit and permitting the infecting contents to spread themselves over the area which has been laid open merely for drainage."

PROPRIETARY MEDICINES AND LEGISLATION.

No doubt something ought to be done by the various State legislatures in the way of regulating the sale of proprietary preparations, and indeed of prohibiting that of some of them, but it is quite obvious that legislation in this direction should not be too arbitrary. If we are correctly informed as to the character of pending legislation in the State of New York, there is danger of its erring in this direction. Among the provisions of the bill "to confer upon the State board of health power to analyze and examine drugs or medicines known as patent or proprietary medicines, and regulating the sale thereof," is one to the effect that no proprietary medicines can be sold after the bill goes into effect, which it does immediately on passing the Legislature and receiving the Governor's signature, until they have been analyzed and passed upon by the board of health. A serious interruption of legitimate trade can hardly fail to be the result of enforcing this provision.

Another objectionable feature of the bill is that there is no appeal allowed from the board's decision. Deservingly as the board is trusted by the medical profession, neither it nor any other body of men should, in our opinion, be clothed with such arbitrary power. The bill ought to be modified, we think, before it is given the force of law.

MINOR PARAGRAPHS.

THE ANNALES D'OCCULISTIQUE IN ENGLISH.

The first number of the American edition of this old and valued journal of ophtalmology has recently reached us. It is the issue for January, 1893, edited by Dr. George T. Stevens and published in New York. Its outward appearance is quite that of the French edition.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 12, 1893:

The Relation of the Medical Profession to Temperance Legislation was the title of a paper read by the Hon. Austin Abbott before the Society of Medical Jurisprudence on Monday evening, the 11th inst. The author discussed several propositions which were original with him and of interest, he said, to the public as well as to the two professions of law and medicine, and among others the following:

"The administration of law touching inebriety as a factor in dealing with crime and public order should be under direct medical supervision."

"The correctional dealing with inebriates should be no longer merely punitive, but put under medical charge for the purpose of further scientific investigation."

"The traffic in liquor should be subject to better medical supervision to diminish adulteration and the sale of intoxicants as proprietary medicines."

"The question of license or tax should be considered with a view to the best medical opinion as to the burdens on the public treasury resulting from inebriety through consequent crime, pauperism, etc."

"The education of the community to an intelligent individual self restraint should be aided by medical instruction systematically provided for by the State, in the common school, and otherwise."

The New York Cancer Hospital, the Decorative Art Society, and the Virginia, Memorial, and Jewell Day Nurseries are to be aided by a loan exhibition of lace, fans, embroideries, tapestries, old silver, jewelry, watches, snuff-boxes, carved ivories, book-bindings, etc. The exhibition will be held in the Ogilvie Galleries, 366 Fifth Avenue, in April, and will remain open for three weeks.

The New York County Medical Association.—At the next meeting, on Monday evening, the 18th inst., a paper on The Modern Treatment of Laryngeal and Pulmonary Tuberculosis, by Dr. Carl von Ruck, of Asheville, N. C., and Dr. J. W. Glotzmann, of New York, is to be the special order.

The Death of M. Dujardin-Beaumetz, the well-known Paris clinician, is announced as having taken place on February 15th. He was in his sixty-first year.

The Death of Mr. John Whitaker Hulke, F. R. S., president of the Royal College of Surgeons of England and senior surgeon to the Middlesex Hospital, occurred on February 12th, after a brief illness. Mr. Hulke was sixty-four years old.

The Kings County Medical Association has elected officers as follows: President, Dr. J. C. Bierwirth; vice-president, Dr. N. W. Leighton; recording secretary, Dr. F. C. Ravor; corresponding secretary, Dr. H. C. Riggs; treasurer, Dr. E. H. Squibb; elected members of the executive committee, Dr. Jonas-
than Wright. Dr. J. D. Rushmore, Dr. R. M. Wyckoff, and Dr. T. M. Rochester.

Changes of Address.—Dr. Edmund E. Blauw, to No. 285 Franklin Street, Buffalo; Dr. Fred J. Broackway, to No. 183 West Seventy-third Street, New York; Dr. Ogden C. Ludlow, to No. 2309 Seventh Avenue, New York; Dr. William Moor, to No. 103 West Fifty-eighth Street, New York.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 23 to March 9, 1895:

McMullen, Frank T., First Lieutenant and Assistant Surgeon, is granted leave of absence for six months on account of sickness.

De Shon, George, First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Logan, Colorado, and ordered to duty at Fort Deshaz, Utah.

Walker, Freeman V., Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect upon his relief from duty at Fort Tomahawk, Conn.

Cleendin, Paul, Captain and Assistant Surgeon. The leave of absence granted for seven days is extended twenty-one days.

The Attending Surgeon at Boston, Mass., will attend the sick at Fort Warren, Mass., during the absence of Captain Cleendin.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the three weeks ending March 9, 1895:

Biddle, Clement, Passed Assistant Surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

Atlee, J. W., Passed Assistant Surgeon. Ordered to the Naval Hospital, New York, N. Y.

Hesler, F. A., Passed Assistant Surgeon. Ordered before the Retiring Board.

Hoebling, A. A., Medical Director. Detached from the Naval Hospital, Chelsea, Mass., and granted three months sick leave.

Farnholt, Amex, Assistant Surgeon. Detached from the Norfolk Navy Yard and ordered to the U. S. Steamer Baltimore.

Kinderberger, C. P., Assistant Surgeon. Detached from the U. S. Receiving ship Vermont and ordered to the Norfolk Navy Yard.

Denbri, Arthur W., Assistant Surgeon. Detached from the Naval Laboratory and Department of Instruction and ordered to the U. S. Receiving ship Vermont.

Park, J. B., Medical Inspector. Detached from duty in connection with the investigation of the Ford Theater disaster and ordered to the hospital and yard, Portsmouth, N. H.

McMemtrie, D., Medical Inspector. Ordered, in addition to his present duties, to duty in connection with the investigation of the Ford Theater disaster.

Richards, T. W., Assistant Surgeon. Detached from Naval Laboratory and Department of Instruction and ordered to the U. S. Steer-up Ship Minnesota.

Stoughton, James, Assistant Surgeon. Detached from the U. S. Steamer Minnesota and ordered to the Puget Sound Naval Station.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine Hospital Service for the Thirteen Days ending February 28, 1895:

Kallioch, P. C., Passed Assistant Surgeon. Directed to rejoin his station at Cincinnati, Ohio. February 21, 1895.

CARVER, H. R., Surgeon. To assume temporary command of Cape Charles Quarantine during the absence of Passed Assistant Surgeon T. B. Perry. February 27, 1895.

Perry, T. B., Passed Assistant Surgeon. To proceed to Brunswick, Georgia, Quarantine, for temporary duty. February 27, 1895.

BLUE, REED, Assistant Surgeon. To proceed to San Francisco, California, for duty. February 22, 1895.

Society Meetings for the Coming Week:

Monday, March 18th: New York Academy of Medicine (Section in Ophthalmology and OtoLOGY); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesday, March 19th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Kings, N. Y.; Baltimore Academy of Medicine.

Wednesday, March 20th: Medical Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

Friday, March 22d: Yorkville Medical Association, New York (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Pathological Society.

Saturday, March 23d: New York Medical and Surgical Society (private).

Births, Marriages, and Deaths.

Married.

MCPHERSON—CORNISH.—In Fort Atkinson, Wisconsin, on Thursday, March 7th, Dr. E. Melvin McPherson and Miss Corn May Cornish.

Burrington.—In Brooklyn, on Thursday, March 7th, Dr. Benjamin Burrington, in his forty-seventh year.

Bu Boas.—In New York, on Saturday, March 9th, Dr. Robert Ogden Bu Boas, in the thirty-sixth year of his age.

Field.—In New York, on Friday, March 8th, Dr. Matthew F. Field, aged forty-one years.

Letters to the Editor.

THE FIRST AMERICAN SYMPHYSOTOMY (1889).

Philadelphia, March 11, 1895.

To the Editor of the New York Medical Journal:

Sir: The editorial of the Philadelphia Medical News, to which Professor Charles Jewett, of Brooklyn, refers in your issue of March 2d inst., was not written or inspired by me, as
he appears to have conjectured. I saw it for the first time when in proof, and then appended a postscript. Dr. Gould wrote of his own option, and we both credit Dr. Joel O. Williams with the Denison operation of April, 1880. The subject of this pubic division was alive and well in Texas last month, and her son, of more than half her age, is a well-grown lad of nearly fifteen years. Dr. Williams never professed to have "fol-
lowed the example of Morisani." The operation was as original with him as it was with Sigault. The reading of Severin Pineau's book gave the idea to Sigault, and the division of the symphysis in a Cincinnati dissecting room taught the same to Williams, who had never heard of Sigault or Morisani or of symphysiotomy as performed by them. He operated on an undeveloped girl of thirteen, and with a George Tienmann tenotomy knife. Dr. Williams sent for a consulting physician of the town, and, failing to get him, was obliged to operate without a medical witness. The pregnancy being illegitimate and in a childlike subject, Dr. Williams kept the secret of the family, as he felt under obligation to do, and hence the long in-
terval between the operation and its report. Dr. Williams is a country surgeon, with nerve enough to do very bold work, and he has been obliged to do such work at times with non-
professional aid. If we were to discredit all obstetric surgery performed under such circumstances, we should be obliged to reject some very reliable Casarean cases that have been long unquestioned.

ROBERT P. HARRIS, M.D.

THE CHARcot MONUMENT FUND.

New York, March 11, 1895.

To the Editor of the New York Medical Journal:

Sir: The following is a statement of the contributions re-
ceived to date to the Charcot Monument Fund:

New York City.

Dr. E. C. Seguin.......................... $50 00
Dr. M. A. Starr.......................... 50 00
Dr. E. D. Fisher.......................... 50 00
Dr. C. L. Dana.......................... 20 00
Dr. C. A. Herter.......................... 50 00
Dr. A. Jacobi............................ 10 00
Dr. Frederick Peterson.................. 10 00
Dr. B. Saels............................. 25 00
Dr. George W. Jacoby................... 10 00
Dr. Ralph L. Parsons.................... 5 00
Dr. J. A. Booth.......................... 2 00
Dr. J. F. Terriberry...................... 2 00
Dr. D. Webster.......................... 1 00
Dr. S. B. Lyon.......................... 5 00

Philadelphia.

Philadelphia Neurological Society...... 150 00

Baltimore.

Dr. William Osler........................ 50 00

Pittsburgh.

Through Dr. T. Dilks........................ 58 00

Montreal.

Through Dr. James Stewart................ 19 00

Boston.

Dr. J. J. Putnam.......................... 5 00
Dr. P. C. Knapp.......................... 5 00
Medico-psychological Society.............. 25 00

Buffalo.

Through Dr. J. W. Putnam................ 15 00

Denver,

Through Dr. H. T. Pershing.............. $10 00

St. Louis.

Dr. L. Bremer........................... 10 00

Chicago.

Dr. A. Church........................... 5 00

Total .......................................................... $642 00

It is desirable that persons wishing to add to the fund send their contributions without delay.

A. C. Helper M. D. Secretary, 819 Madison Avenue.

THE TAIT-HART AFFAIR.

To the Editor of the New York Medical Journal:

Sir: An extract headed "From the New York Medical Jour-
nal," dated 9th February, 1895, Mr. Lawson Tait and his Pro-
fessional Brethren, has come to our notice.

As solicitors for Mr. Ernest Hart, whose name is therein
mentioned, will you allow us, in the absence of that gentleman, who is still in India, to inform you that in the month of No-
ember, 1894, Mr. Lawson Tait commenced an action for slander against our client, Mr. Hart, claiming £10,000 damages; that on this coming to Mr. Hart's knowledge he, without waiting to be served with the writ, instantly appeared and demanded a statement of claim; that on the 12th December, 1894, we received from Mr. Lawson Tait's London agents a notice of dis-
continuance of the action, and that our client's costs thereof have since been paid by the plaintiff?

A. H. ArnoLD & Son, Solicitors for Mr. Ernest Hart.

Proceedings of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-ninth Annual Meeting, held in Albany, on Tuesday, Wednesday, and Thursday, February 5, 6, and 7, 1895.

The President, Dr. George Henry Fox, of New York, in the Chair.

(Continued from page 228.)

Thirty-nine Cases of Strangulated Hernia and the Les-
sions Taught by them—Dr. W. B. De Garmo, of New York, read a paper with this title.

In twenty-two of these cases reduction had been effected without operation; in the remaining seventeen operative measures had been employed, and in three of them death had resulted. Taxis, as the term was ordinarily used, had no definite meaning. The author's method of reduction consisted of two factors, traction and compression. The patient was placed upon a table or other unyielding surface, manipulation without violence was practiced at the neck of the tumor, the latter being drawn forward, then with careful and graduated compression the tumor was slipped back through the canal. This method relieved the congestion of the tumor, forced back the gas, and, if properly carried out, was unlikely to rupture the intestine. An anesthetic was not administered unless a cutting operation
was to be performed at once. Externally only one should be used, and this was frequently effective, especially if the tumor was composed largely of omentum. Hypodermic injections of morphine should be given only with the view of relieving severe pain; they sometimes masked the actual condition of the patient. In several of the author's cases the patients operated upon had been more than seventy years of age; extreme age was not, therefore, necessarily a contraindication to the operation. After the bowel had been exposed it was well to apply very hot water to it; this would frequently restore the equilibrium of the circulation in cases in which great congestion was present and in which gangrene appeared imminent. If an operation was to be performed it should be done promptly and would often result in saving life. The percentage of cases fatal from the operation was small. In young children reduction was usually possible without a cutting operation. Roughness of manipulation was always to be avoided; it would be almost certain to do more harm than good. A cathartic should not be given after the return of a damaged bowel.

The Symptomatology of Cerebellar Disease.—Dr. W. C. Krasse, of Buffalo, who reported four cases and showed specimens from them, said that in 1892 Luciani had made the most important contribution ever made to the subject of cerebellar disease, abandoning all previous landmarks and studying the subject ab initio after having removed a dog's entire cerebellum successfully. All observers were in agreement that the cerebellum played no part in the functions of the mind. The sexual instinct did not reside in the cerebellum in the sense in which it had been announced by Gall. The problem of the entire field of utility of the organ was still far from solved. Crossed action had been definitely determined in its function, and it was also certain that after its removal the movements of the lower extremities were interfered with. It had also been determined that as a center it presided over the co-ordination of movement. Some of the phenomena attending its injury were headache, optic neuritis, inclination to turn the head toward the side of the lesion, and tremors. The sexual appetite and some other functions were also more or less disturbed.

Abnormal Facial Development was the subject of a paper by Dr. Sumner Hayward, of Rochester, whose investigations had led him to the conclusion that abnormalities in facial development resulted from some defective function or functions. One of the most potent causes to produce change in the facial outline was mouth-breathing. The necessity of relieving obstruction in the upper air-passages in early life was therefore apparent.

The Prevention of Hernia after Laparotomy.—Dr. H. S. Durand, of Rochester, criticised the method of making a very short incision in abdominal operations, especially in those performed for appendicitis, also the want of careful attention by some operators to cleanliness of the hands. Apparently insignificant factors sometimes decided the course which a wound would take. After the wound had been closed the author's custom was to take a piece of crêpe bandage sufficiently large to cover the wound, two or three folds thick, and furnish with a double row of ordinary dressmaker's hooks securely fastened to the crêpe. The latter was then secured to the surface of the body over the wound with collodion, and the hooks on opposite sides were approximated to each other by strong silk, as one would lace a shoe. The traction thus exerted would relieve the strain upon the tissues contiguous to the wound and also prevent undue tension on the scar which formed. This could be removed when the sutures from the wound were removed, or it could be applied then for the first time, and it could be retained in position several weeks or months with advantage and without discomfort.

Inversion of the Appendix Verniformis.—Dr. G. M. Ee- noms, of New York, read a paper in which he said that the present methods of closing the opening in the stump of the appendix were objectionable, as infection was not impossible with any of them. The method which he proposed was to invert the stump after a portion of the appendix had been removed, or the whole of it in cases in which none had been removed, thus bringing the entire organ, after releasing it from its mesentery, into the lumen of the colon. The opening left in the peritoneum was to be brought together with a running or purse-string suture. In chronic inflammation of the appendix such an operation was believed to be very desirable. The procedure was not difficult and was preferable to amputation. The inversion should be begun with the fingers at the proximal end, and concluded by forcing the extremity into the invaginated portion with a dressing forceps. As to what would happen afterward to the appendix in its new situation, that was a matter of no practical importance. Theoretically, it should slough away, as its nutrition would be cut off.

Dr. Macdonald, of Albany, thought the present methods of treating the stump were sufficiently safe to warrant their continuance. In his own practice no fascial fistula from the stump had ever resulted, and he thought such an occurrence improbable. The method proposed would be impracticable if the appendix was strictured, as was not infrequently the case, and also in some cases in which adhesions were present. In suppurative cases infection might be transferred to the interior of the bowel. General infection from the small wound in the stump of an appendix was a very remote possibility and need not be feared.

Dr. J. G. Clark, of Olean, thought the method proposed a most unnatural procedure, and believed that we should imitate and not deviate from Nature's methods in our surgical measures.

Dr. E. N. Liiell, of New York, had seen the advocate of the procedure perform it in three cases, and conceded the merit that it would certainly obviate the possibility of infection from the stump.

Dr. Fiske, of New York, was not convinced that any advantage could be gained by the proposed method of invagination. The only case with which he was familiar in which it had been tried had resulted fatally.

Dr. H. J. Boldt, of New York, thought that in the ordinary suppurative cases the operation in question was inapplicable.

Dr. A. F. Currier, of New York, differed with Dr. Edelblad as to what would happen to the appendix being a matter of indifference or insignificance. If it floated free within the colon it would be quite likely to arrest the fecal current and might cause fecal accumulation, impaction, and a renewal of the inflammatory symptoms for which the original operation had been performed. It was his belief that a very large number of cases diagnosed as appendicitis arose primarily from such a disturbance of the intestinal function. It was by no means certain that the incarcerated member would either atrophy or slough, and he thought the experiment a very dangerous one.

A New Method of Closing the Abdominal Wound after Celiotomy was the title of a paper by Dr. R. Waldo, of New York. As hernia was the most common accident after abdominal section, he said, many methods had been devised to secure the abdominal wound. Some of these were referred to in detail. The method which was proposed consisted in a layer of deep sutures involving all the tissues, entering the skin an inch beyond the wound and emerging through the peritoneum near its cut edge, and an intermediate row which should include the
skin, fat, and upper layer of fascia of the recti muscles. No sutures were to be buried, and if suppuration occurred it could readily be detected and the offending suture removed.

Dr. Boldr dwelt on the importance of using all possible means of preventing ventral hernia, and said that any method of suturing which favored union of the wound by first intention would to that extent be useful and desirable.

Dr. Currier believed that no method of closing the abdominal wound was perfect. Many factors were involved in the procedure. If the tissues had been extensively bruised, suppuration would probably result, and this would, of course, weaken the resulting scar. The method suggested was similar to Wylie's in including the fascia of the recti, and was an improvement, inasmuch as all the sutures were accessible in case the healing process was in any way abnormal.

(To be continued.)

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of December 12, 1894.

Climatology in Cirrhotic Rhinitis.—Dr. Robert Binder read a paper on this subject in which he remarked that the pathological changes in atrophic rhinitis presented a subject for much controversy—pathologists differed in their a priori investigations. Therefore a clinical a posteriori reasoning was accomplished under difficulties which induced fractionalism as to whether the tissue metamorphosis was the result of a progressive hypertrophy, or whether it had its own isolated causes classing it as an affection per se. Nevertheless, we had a cirrhotic state to combat. Let it be the result of hypertrophy, as alleged by some, or the result of a pathogenic coccus or bacillus, as accounted by others, it still maintained the same course that scleroses did in other organs. This was a prolific development of tissue cells, in various stages, from round cells to developed caciectricis, causing caceous degeneration of epithelium, which result was directly due to a progressive contraction. This contraction, while homologous to the scleroses in other organs, owing to the situation, was more accessible and, consequently, more amenable to treatment by atmospheric changes, and directly subject to increased exacerbations when the surroundings were unfavorable. The speaker felt complacent over the fact that climate revealed to him measures of pronounced success in the amelioration and possible cure of this odious disease. As for local applications, his experience had been futile, although, at the same time, he had persevered. He did not doubt that this was the experience of all practitioners in the treatment of this stubborn malady; hence it behove the thoughtful rhinologist to consider some method which would enable him to place the patient upon a vantage ground where the morbid changes would be inhibited and the remnants of healthy tissue and glands would be stimulated to normal physiological action, overcoming gradually a lesion that had defied medical treatment.

The paramount evil was apparent in this affection as in all chronic diseases—social ostracism. Truthtfully, it was more apparent here than in some others; the offensive smell which was noticeable in the large majority of cases not only rendered the patients unfit for many offices, but it must be constantly a reminder of their infirmity, inducing melancholy and other psychical phenomena. The results of this condition could be depicted by observing physicians; that deplorable state which they had seen among the hopeless—the epileptics, the maimed, the phthisical, and the insane. Since colonization had done more as a restorative to the epileptics than medicinal or operative measures had, and since the healthy offspring of the tuberculous immigrant in Colorado demonstrated what could be done for the afflicted who feared Nature's law of heredity, the scientific climatologist conjectured wisely when he considered "what might be done for the chronic invalid in colonies, established in suitable places, and arranged politically, that they might compete with their fellows for a livelihood." This would be not only a step toward Utopia, but a lesson of philanthropy that could only be accomplished by the highest grade of civilization, urged and abetted by a compassionate humanity. Moreover, when morphology—and this referred more especially to morphological keratony and embroyology—was established systematically in medical diagnosis, the treatment of many chronic diseases would resolve itself into colonization. The reason of this was patent, for the profession would recognize more explicitly causes of evolution and also those of atavism.

Ozona, the prevailing symptom, although sometimes absent—as the speaker had seen it—was by no means diagnostic of the condition. Ozona might be the result of tuberculous, syphilis, and various ulcerations, and even a result of accessory disease, although Drake had originally maintained that atrophic rhinitis never existed unless accompanied by antral, ethmoidal, or sphenoidal disease. Since, according to Dr. Binder's view, the ozona was due to caseous degeneration of epithelium, this symptom, he said, was entirely dependent upon the intensity of the cirrhosis, and, according to Dr. E. Frankel's and Dr. Krause's theory, the diathesis and environments which favored the propagation of the Bacillus fadius. Why the Bacillus fadius evinced itself in some cases and not in others was a question that should be settled by the bacteriologists. The clinician was fully aware that the diathetic, surroundings, and other incidents dependent upon the vocation of each patient augmented the development of this bacillus. Moreover, the site of the lesion was in itself a septic location, which was modified by the anatomical conformation of each individual's nose which was unfortunately attacked. This truth was another clew which the morphologist could employ in the revelation of the mysteries of anomalies and reversions. He had seen the typical nose of the anatomist's chart in clinics, but he had never seen two identical nasal chambers in either a physiological or a pathological state. Therefore the normal structure, prior to the pathological development, was the foundation upon which the intensity of the lesion depended; hence the peculiarity of each individual case.

The turbinates were the sites by preference for the morbid change in the atrophy of the nasal organs, and the classical seat in the major portion of the cases which had come under the speaker's notice had been the inferior and septal portion of the middle bone. Recent investigations had disclosed that the inspired air passed through the middle meatus, and that, this was normal respiration. These investigations revealed to the climatologists the danger of vitiating air to an atrophic condition upon the middle bone. Hence the patient must have an ozonized air—air free from sulphurous-smoke and noxious vapors of every description. In short, urban air, with its sooty and dusty composition, must be avoided in order not to increase the symptoms. There were three kinds of atmosphere admissible in the treatment; they were suburban, mountain, and sea air. The choice depended entirely upon the circumstancies—e. g., patients dwelling in large cities near the sea or in seaport towns should be sent to the highlands and to places where the relative humidity was less than sea level. On the other hand, patients dwelling inland (the speaker would not say on highlands, for mountaineers were particularly free from atrophic rhinitis) should be sent upon sea voyages in order to derive full benefit. The suburban localities he mentioned only as palliatives for extreme changes, as some patients could not afford, for pecuniary
reasons, to go farther than the counties adjacent to their respective homes. However, he recalled one case in which the patient had improved in the two months' time spent in the Schuykill Valley, the desiccation of the secretions and the odor being curiously when he had returned for treatment. The cases which were beyond climatic therapy were generally those of patients who presented the most advanced lesions, but financial reasons had prevented them from receiving the full benefit of treatment and advice. These were the cases that colonization would aid.

The ideal course in the climatology of this affection depended entirely upon the case in vogue. First, the general condition of the patient must be considered—e.g., was anemia present? According to Dr. Binder's observation, it was in a large percentage of cases. He accounted for this morbid condition in the following manner: The lesion involved the nasal portion of the respiratory tract, and, in his estimation, any lesion implicating this tract, whether in the peripheral or in the central portion, prevented proper aeration of the blood. Hence the anemia varied proportionately to the amount of tissue involved in this cicatrizing process. Notwithstanding, the anemia should be treated with hematinics and a bracing atmosphere, in which there was an abundance of oxygen; the mountains of Pennsylvania and New York in summer, and the Atlantic seaboard in early spring fulfilled these requirements. Secondly, the patient's temperament should be considered. He would divide disposition into two states: irritability and repose. The general rule was that persons with a light complexion belonged to the reposed in temperament, while persons with a dark complexion were irritable. In the selection of an abode for health for the afflicted, this statement must be well borne in mind, as it was of the utmost importance to send the irritably inclined to climates which were of a sedative nature. Contrarily, the solid should be sent to stimulating resorts, where animation would cause them, in part, to forget their malady.

The primary requisite in promoting the domination of the healthy tissue and fostering a metamorphosis in the disorganized structure in all cases was outdoor life; not for a definite length of time each day, but, if it was possible to remain in the atmosphere twenty-four hours, it would do the better accomplish the desired result. The sleeping apartment should be roomy, and a free circulation of air should be active during the sleeping hours as well as when the room was unoccupied. Above all, steam radiation should be avoided. The dry air should be eschewed at all times, for the reason that the sufferer with cicatrizing rhinitis—unless the pathological surface was of small area, and this he had never seen—could not infuse the inspired air with sufficient moisture to insure a salutary influence upon his economy. Extreme cold should be shunned, and also localities that were extolled for dryness—such, for example, as Colorado and New Mexico, in the United States, and Egypt abroad. One of the worst evils which characterized these places was the violent sand storms, causing a mechanical irritation to a membrane passing through the various stages of chronic inflammation, and also causing a painful naso-pharyngitis. In all cases that had come under his notice in Philadelphia, subjectively and objectively, the disease had been augmented during the long dry and cold spells. Contrarily, the summer months, especially the moist, warm days, benefited and relieved the patients and checked the process of destruction.

The abode and climate of preference, from which superior results would be obtained, was one the qualities of which consisted of picturesqueness, warmth, balminess, equability, and stimulant or sedative properties (according to the temperament of the patient). Picturesqueness afforded solace to the restless and fostered a feeling of joy and careless demeanor in those who were morose. In fact, there was nothing so free of sickly contamination as an ever-varying landscape.

Warmth was the next quality which the speaker recommended; and by warmth he meant a temperature of over 70° F., and it might range to 84° F. This was requisite for two reasons: it aided in moistening the inhaled air, and, owing to its mildness, the small amount of healthy tissue could perform its function admirably. Cold air, on the other hand, not only could not impregnate itself with moisture, but it was deleterious to the healthy membrane, and caused its hasty destruction. The second reason for warm air was the opportunity that it afforded for outdoor exercise, without bundling in swaddling clothes, which impeded free circulation and interfered with the glandular system. This system must be kept as nearly perfect as possible if a cure was to be hoped for in rhinitis cicatrization. Moreover, accompanying this affection, or rather as one of the sequelae, was a functional disturbance of the nasal organ, due to agglutination of the months of the Eustachian tubes in the naso-pharynx. The dripping of viscid mucus from the nose was responsible for this plastering process. Warmth, combined with a moderate relative humidity, was not only a preventive of this troublesome symptom, but a positive relief in cases of some length of duration.

Balminess was a combination of moisture and sunshine tempered with warm currents such as would be blown from the ocean by light breezes, and experienced in resorts along the southern coast of California, the eastern shores of Italy, and that delectable country of southeastern France and adjacent Italy washed by the shores of the Mediterranean Sea. It insured the patient from the fear of catching cold, and for this reason allowed him to take outdoor exercise with a feeling of immunity. The moisture in a balmy atmosphere was due to the degree of relative humidity; the latter was directly dependent upon the influence that the absolute humidity had upon the temperature. Since warmth was a component part of the climate he had recommended, it was well to observe that an extremely damp locality should be avoided, for the results which were to be obtained from moisture would not be forthcoming, but instead the patient would suffer from a high degree of relative humidity. In order to avoid excessive humidity, it was well, according to meteorological observations, to eschew extreme temperatures.

The equality of which Dr. Binder had spoken as a factor in the selection of a suitable domicile for atrophic conditions of the nares applied, he said, more to the equality of the warmth which he had already described. Coasts or islands washed by warm ocean currents were to be mentioned as possessing equality. Truly all large bodies of water averted the rapid rise and fall of the temperature wave, although the confines of the Great Lakes of America were visited by most severe rises and falls of temperature in a short period of time, and the direct cause of this, he thought, was the plateau-like situation of these lakes, as this was not true of Salt Lake, which was in a basin although elevated at the same time some 4,000 feet.

It was with some regret, he said, that he spoke of sea voyages, knowing that there was not the desired facility. There were no planned voyages by steamers departing from any of our seaports for southern sea benefits, calling at stations of interest and salubrity, that the only expedient was a sojourn upon one of the islands in the Atlantic Ocean, such as the Bermudas, Azores, or Madeira Islands, which combined equality and sedativeness.

The last qualities that were necessary considerations in the choice were influences which bore upon the corporeal and mental faculties of the individual; they were sedativeness and a stimulant character. He had previously classed the variety of
patients who improved best in climates possessed of one or the other of these attributes. Sedentiveness would be found in localities or resorts whose air was balmy, mild, and bright, and whose elevation must not exceed four hundred feet above sea level. As stated before, the following islands were unwavering examples of this character: the Bermudas, the Azores, and Madeira. Stimulation was found at high altitudes, ranging from five hundred feet to a mile above sea level. Of the resorts which combined equability and a stimulant action he mentioned Nice, Mentone, Cannes, and Villefranche on the shores of the Mediterranean; but, according to many climatologists, the islands in this sea were superior—Capri, Malta, Majorca, and Sardinia. In the Atlantic Ocean the Canary Islands were noted for their stimulating attributes, and in the Pacific mention might be made of Western Australia. The southern coast of California had an atmosphere the volume of which was equal and stimulating. The counties of that State bordering on the ocean were Santa Barbara, Ventura, Los Angeles, and San Diego. All these resorts had improved hostelries, and home comforts could be partaken of very liberally. Therefore the physician need not hesitate to give his patients advice against them owing to lack of accommodations.

Dr. Binder stated that recently in two cases of atrophic rhinitis tuberculosis of the lungs had developed. Therefore it appeared to him that there must be fibroid changes in other organs, following the progress of the disease in the nose; or, while the destruction was active in the nasal organs, it was a suitable and favorable opportunity for the ingress of the tubercle bacillus. If this presumption could not be refuted, we had additional reason to treat this affection upon a climatic basis, both to prevent this result and to hasten the subsidence of the nasal lesion.

_Clinical Lectures and Essays on Rickets, Tuberculosis, Abdominal Tumors, and other Subjects._ By Sir William Jenner, Bart., G. C. B., M. D. Lond., F. R. C. P., etc., Physician in Ordinary to the Queen, Consulting Physician to University College Hospital, New York: Macmillan & Co., 1895. Pp. 3-322. [Price, $4.]

This volume is almost unique in medical literature. It is a collection of lectures most of which were delivered thirty years ago, now published without revision as they were then written. It not only evinces courage on the part of the author, but proves that accurate clinical observations never grow old and are as correct at one time as at another. Rickets was the same forty years ago that it is to-day, and Sir William Jenner's genius enabled him to see at that time practically all that observers have seen since. It is true that recent observations have taught us much regarding the etiology and histology. Men of the younger generation frequently fall into the error, however, of supposing that all that is known of medicine is of recent date. The statements often heard regarding the revolutionizing of medicine by modern research are proved by works of this character to be entirely too sweeping. This little book furnishes much food for reflection. The lectures on rickets, which were delivered in 1829 and 1869, will be found to present nearly all the knowledge regarding the clinical aspects of that disease which we possess to-day. It is true that scurvy and rickets were not clearly distinguished, but laryngismus and carpo-pedal contractions, of which so much has been said in recent years, are fully considered. The author's clinical descriptions are graphic and often intensely interesting. In this regard he has long been considered a master. Except in the minor details in which historical research has changed our ideas somewhat, the author's description of rickets forms as profitable reading to-day as it did thirty-five years ago.

Five lectures are devoted to abdominal tumours, and they were delivered in 1869 and 1870. The first is devoted to methods of clinical observation and physical examination. Taken together, these lectures form a very complete and most satisfactory work upon this important subject and upon physical examination of the abdomen.

In the lectures on scrofula and tubercle, although we now know that the ultimate pathological products of the two are identical, the author still holds that the constitutional states which precede the local manifestations are of a different type and deserve separate consideration. Taken as a whole, if it had no other result, the work would demonstrate very clearly the reasons for the high regard in which Sir William Jenner has so long been held by the medical world.

**Surgical Nursing.** By Bertha M. Yoswinkel, Graduate of the Episcopal Hospital, Philadelphia. With One Hundred and Eleven Illustrations. P. Blakiston, Son, & Co., 1895. Pp. xiv-9 to 168. [Price, $1.] The author of this little work says that it has been written for that large body of nurses whose technical education is not sufficiently advanced to enable them thoroughly to master the subject of general nursing. We do not understand how a nurse can become a really efficient surgical nurse who is not a competent general nurse. The most satisfactory specialist is the one who has developed from the general practitioner. Whatever the author's object may have been, the result is extremely satisfactory. Her book contains in very concise and practical form a large part of the special knowledge which the surgical nurse should possess. The chapters devoted to antisepsis and antiseptic dressings are especially good. The work must prove, on the whole, a valuable one for the general nurse who wishes to become proficient in modern surgical work.

This little book gives the symptoms of the various diseases of the eye in tables of parallel columns, thus presenting to the reader at a glance the principal diagnostic features. In other words, the sifting of the larger text-books, which is wearisome sometimes to a degree, is here done for the practitioner better than would be possible for any one not skilled in eye diseases.

On Digestive Protocols; being the Cartwright Lectures for 1894. Delivered before the Alumni Association of the College of Physicians and Surgeons of New York. By R. H. Chittenden, Ph. D., Professor of Physiological Chemistry in Yale

Die Diathesie. Von Dr. A. Baginsky. [Separatabdruck aus der Real-encyclopädie der gesamten Heilkunde.]

Morphology as a Factor in the Study of Disease. By Harrison Allen, M. D. [Reprinted from the Transactions of the Congress of American Physicians and Surgeons.]

A Study of the Mode of Action of Ilethkyd in Inflammatory Conditions. By D. Braden Kyle, M. D. [Reprinted from the Therapeutic Gazette.]

The Treatment of Syphilis with Intravenous Injection of Mercenric Chloride. By Walter Lytle Pyle, M. D. [Reprinted from the Medical News.]

The Prevention and Treatment of Ophthalmia Neonatorum, and the Necessity for more Efficient Legislation to Prevent Blindness from this Cause. By Charles H. May, M. D. [Reprinted from the Medical Record.]

Bacteriological Study of Four Cases of Diphtheria treated with Antitoxine by Dr. Louis Fischer at the Municipal Hospital, Philadelphia. By D. Braden Kyle, M. D. [Reprinted from the American Journal of the Medical Sciences.]

Cylindroma Endothelioides of the Dura Mater causing Localizing Symptoms and Early Muscular Atrophy. By L. Bremer, M. D., and N. B. Carson, M. D., of St. Louis. [Reprinted from the American Journal of the Medical Sciences.]

A Case of Fracture of the Thyroid Cartilage; Recovery without Tracheotomy. By Thomas B. Eastman, M. D., of Indianapolis. [Reprinted from the Journal of the American Medical Association.]

Ophthalmia Neonatorum. By C. A. Vecsey, M. D., of Philadelphia. [Reprinted from the Medical News.]

**Miscellany.**

The Influence of the Force of Gravity on the Circulation.—In No. 312 of the Proceedings of the Royal Society there is an abstract of a paper on this subject by Mr. Leonard Hill, of London, who remarks that the effect of position of the body upon the circulation of the blood is a matter of daily observation with the physician and surgeon, but that it has been curiously neglected by physiologists. So far, he says, as his researches into the history of the subject go, the mere fact that the feet-down posture lowers arterial pressure, and that the feet-up posture heightens it, is almost all that has been determined. The author's attention was first drawn to the influence of gravity upon the circulation by observations which he had made upon the normal intracranial tension in a patient who had been treated. Mr. Hill found that the pressure was negative while the man sat upright, but that it became positive as soon as the head was bent down toward the knees and on any inspiratory effort. The air-bubble index in the apparatus showed large cardiac and respiratory undulations.

The research, says the author, has been carried out upon rabbits, cats, dogs, and monkeys, and the same general results have been obtained from all. The animals were anesthetized in all the experiments and were placed upon a board with the limbs fully extended in the same direction as the longitudinal axis of the body. The venous pressures were recorded by means of a manometer filled with a saturated solution of manganese sulphate and placed in connection with a delicate tambour or piston recorder. The cerebral pressure was taken in the toecorel Herophilus by the method described by the author in No. 35 of the Proceedings of the Royal Society. The respiratory tracings were taken by means of a broad band of strapping passed around the thorax and connected to either side of a Paul Bort tambour. The results of the research are shown in a series of tracings from which the following conclusions are drawn:

1. The force of gravity must be regarded as a cardinal factor in dealing with the circulation of the blood.

2. The important duty of compensating for the simple hydrostatic effects of gravity in changes of posture must be ascribed to the splanchic vaso-motor mechanism.

3. The effects of changing the posture afford a most delicate test of the condition of the vaso-motor mechanism.

4. The amount of compensation depends largely on individual differences.

5. The compensation is far more complete in upright animals, such as the monkey, than in rabbits, cats, or dogs, and, therefore, is probably more complete in man.

6. In some normal monkeys over-compensation for the hydrostatic effects occurs.

7. In the normal monkey and in man gravity excerts but
little disturbing influence, owing to the perfection of the compensatory mechanism.

8. When the power of compensation is damaged by paralysis of the spinal nerve-constrictors induced by severe operative procedures, by injuries to the spinal cord, by asphyxia, or by some poison, such as chloroform or curare, then the influence of gravity becomes of vital importance.

9. The feet-down posture is of far greater moment than the feet-up posture, because, when the power of compensation is destroyed, the blood drains into the abdominal veins, the heart empties, and the cerebral circulation ceases.

10. Generally speaking, the feet-up posture occasions no ill effects.

11. The horizontal and feet-up postures at once abolish the syncope induced by the feet-down posture by causing the force of gravity to act in the same sense as the heart, and thus the cerebral circulation is renewed.

12. Firmly bandaging the abdomen has the same effect. While the heart remains normal, and so long as the mechanical pressure is applied to the abdominal veins, the blood pressure can not possibly fall.

13. If the heart is affected by chloroform or by curare poisoning, the restoration of pressure is incomplete, and it is possible that the heart may be stopped altogether by the inrush of a large quantity of blood caused by too rapid an application of pressure on the abdomen. More work would be thrown upon the heart than, in its impoverished condition, it could perform.

14. Vagus inhibition and cardiac acceleration are subsidiary compensatory mechanisms in the feet-up and feet-down postures respectively.

15. Chloroform rapidly paralyzes the compensatory vaso-motor mechanism and damages the heart.

16. Ether, on the other hand, paralyzes the compensatory vaso-motor mechanism only very slowly and when given in enormous amounts.

17. The vaso-motor paralysis induced by these anaesthetics lasts for some considerable time after the cessation of their administration.

18. Chloroform may, by destroying the compensation for gravity, kill the animal, if it is placed with the abdomen on a lower level than the heart.

19. Elevation or compression of the abdomen immediately compensates for the vaso-motor paralysis produced by chloroform.

20. Compression or elevation of the abdomen, together with artificial respiration and with squeezing of the heart through the thoracic walls, is the best means of restoring an animal from the condition of chloroform collapse.

21. The feet-down posture inhibits respiration, and the feet-up posture accelerates it.

22. These respiratory results probably depend upon the stimulation of sensory-nerv endings by changes of tension brought about by the alterations of posture, because the results are abolished by dividing the vagi.

23. In the feet-down posture the respiration is thoracic in type and the abdomen is retracted; in the feet-up posture the respiration is diaphragmatic and the abdomen is freely expanded.

24. These types of respiration tend to compensate for the effects of gravity on the circulation, for the retraction of the abdomen in the feet-down posture mechanically supports the abdominal veins, while the thoracic inspirations aspirate blood into the heart. In the feet-up posture the full and free expansion of the abdomen withdraws all obstacles to the compensatory dilatation of the abdominal veins.

In the last part of the paper the medical aspects of this research are discussed. It is suggested that emotional syncope is due to paralysis of the splanchnic area, and a case is cited where compression of the abdomen immediately removed the syncopal condition. The same treatment, or that of elevation of the abdomen, is suggested for conditions of shock, for chloroform collapse, and after severe hemorrhage.

The Tri-State Medical Society of Iowa, Illinois, and Missouri.—The next meeting will be held in St. Louis, on April 2, 3, and 4, 1892, under the presidency of Dr. James Moores Ball, of St. Louis. The preliminary programme includes the following papers: Medical Evils, by Dr. W. R. Allisons, of Peoria, Ill.; The Influence of Malaria in Rhinological and Laryngological Work, by Dr. J. R. Ash, of Brighton, Ill.; The Open-air Treatment of Consumption, by Dr. Robert H. Babcock, of Chicago; The Anatomical Renaissance, by Dr. James Moores Ball, of St. Louis; The Use of the Lever in Clubfoot, by Dr. C. W. Barrier, of St. Louis; The Treatment of Trachoma and Trachoma Sequelae, by Dr. Charles H. Beard, of Chicago; Tuberculosis of the Bones, by Dr. D. C. Brockman, of Ottumwa, Iowa; The Uterine Sound and Curette, by Dr. W. M. Catto, of Decatur, Ill.; The Treatment of Functional Dyspepsia, by Dr. J. M. G. Carter, of Waukegan, Ill.; The Recent Advances in Therapeutics, by Dr. David Cernin, of Galveston, Tex.; Food Adulteration—Its Cause and Prevention, by Dr. Charles S. Chase, of Waterloo, Iowa; A Report of a Herniomy, by Dr. J. J. Conner, of Pana, Ill.; Inflammation of the Anal Canal, by Dr. George J. Cook, of Indianapolis; The Diagnosis of Intra-abdominal and Pelvic Pathological Conditions, by Dr. A. H. Corr, of Kansas City; What is Seroful? by Dr. A. C. Corr, of Carlinville, Ill.; The Study of a Family of Four Degenerate Children, by Dr. Richard Dewey, of Chicago; Injuries to the Pelvic Floor, by Dr. F. B. Dorsey, of Keokuk, Iowa; Pleurisy with Effusion, by Dr. H. C. Eschbach, of Albia, Iowa; The Pathology and Treatment of Appendicitis, by Dr. A. H. Ferguson, of Chicago; The Treatment of Stricture of the Rectum, by Dr. S. G. Gant, of Kansas City; The Parasitic Nature of Cancer, by Dr. Henage Gibbes, of Ann Arbor, Mich.; Myositis of the Frontal Sinus, by Dr. W. E. Guthrie, of Bloomington, Ill.; Babies, by Dr. H. A. Hartley, of Keokuk, Iowa; Some Forms of Mastoid Operation, by Dr. R. C. Helbrower, of Cincinnati; The Indications for Laparotomy, by Dr. W. O. Henry, of Omaha, Neb.; Some Thoughts on Elimination, by Dr. T. E. Holland, of Hot Springs, Ark.; Osteal Tuberculosis without Arthritis, by Dr. Bayard Holmes, of Chicago; The Economics and Ethics of Reproduction, by Dr. W. Hutchinson, of Des Moines, Iowa; Nocturnal Pollutions and Spermatorrhea, by Dr. Henry Jacobson, of St. Louis; When Shall we Amputate? by Dr. Webb J. Kelly, of Galion, Ohio; Brain Tumor and its Surgical Treatment, by Dr. Enory Lapham, of St. Louis; Ununited Fractures and Bone Lesions, by Dr. E. R. Lewis, of Kansas City; To Spray or not to Spray? by Dr. H. W. Loeb, of St. Louis; Excision of the Rectum and Colectomy, by Dr. J. M. Mathews, of Louisville; Excision of the Elbow Joint in Children, by Dr. Samuel E. Milliken, of New York; An Address in Medicine—The Relation of Infection to the Nervous System, by Dr. H. N. Moyer, of Chicago; The Electrotherapy of Sexual Neurosis, by Dr. F. P. Norburg, of Jacksonvillle, Ill.; Hysteria and Organic Disease of the Nervous System, by Dr. Hugh T. Patric, of Chicago; Gastric Neurones and their Diagnosis and Treatment, by Dr. H. E. Pearse, of Kansas City; Puerperal Eclampsia, by Dr. A. D. Price, of Harrodsburg, Ky.; The Stigmata of Nervous Diseases and their Utility in Diagnosis, by Dr. John Punton, of Kansas City; Epilepsy—Removal of a Cerebral Cyst, by James Rowland, of Dubuque; Typhoid Fever—Perforation and Operation, by Dr. B. Merrill Ricketts, of Cincinnati;
An Address in Gynecology.—Observations on the Peritonenum in Fifty Autopsies, by Dr. E. Byron Robinson, of Chicago; Ophthalmia Neomatorum, by Dr. E. Orrin Sisson, of Keokuk, Iowa; A Clinical Report on Thyroid Extract, by Dr. Edwin Walker, of Evansville, Ind.; Narcophilia, by Dr. W. F. Vaughn, of Chicago; The Treatment of Chronic Subcutaneous Middle-ear Diseases, by Dr. M. F. Weymann, of St. Joseph, Ill.; Tumors of the Eyeball, by Dr. William H. Wilder, of Chicago; The Hysteric Element in Joint Diseases, by Dr. William E. Wirt, of Cleveland; An Address in Surgery, by Dr. John A. Wyeth, of New York. Papers will be read (the titles to be announced) by Dr. J. F. Binne, of Kansas City; Dr. George W. Cole, of St. Louis; Dr. H. C. Crowell, of Kansas City; Dr. Gilbert L. Culkin, of Cincinnati; Dr. Charles L. Dana, of New York; Dr. Edward P. Davis, of Philadelphia; Dr. W. B. Dewees, of Salina, Kan.; Dr. J. H. Etheridge, of Chicago; Dr. Ferdinand Heuroud, of Chicago; Dr. J. R. Hollowbush, of Rock Island, Ill.; Dr. J. A. J. James, of St. Louis; Dr. Howard A. Kelly, of Baltimore; Dr. B. B. La Force, of Ottumwa, Iowa; Dr. Dransford Lewis, of St. Louis; Dr. J. N. Love, of St. Louis; Dr. G. Frank Lydston, of Chicago; Dr. J. H. McIntyre, of St. Louis; Dr. L. A. Malone, of Jacksonville, Ill.; Dr. A. H. Meinbech, of St. Louis; Dr. George Minges, of Dubuque, Iowa; Dr. F. D. Mooney, of St. Louis; Dr. Adolf Meyer, of Kankakee, Ill.; Dr. H. H. Mudd, of St. Louis; Dr. Paul Paquilo, of St. Louis; Dr. Roswell Park, of Buffalo; Dr. James F. Pouey, of Galesburg, Ill.; Dr. Francis Reder, of Hannibal, Mo.; Dr. John Ridlon, of Chicago; Dr. T. Hanton Steuck, of Louis ville; and Dr. W. N. Wishard, of Indianapolis. Dr. W. W. Keen, of Philadelphia, will hold a surgical clinic, and Dr. Charles A. Oliver, of Philadelphia, will hold an ophthalmic clinic.

Some Rare Forms of Gout.—In the March number of the University Medical Magazine there is a short article on this subject by M. Debout d'Estrees, of Contrevéville, who relates the histories of a few cases that have come under his observation. The first was that of a man, sixty-three years old, who went every year to Contrevéville to obtain the benefit from the evils of excesses he was not yet able to control. The patient said that after sitting for a long time at his dentist's, the day before, he had been seized during the night with an intense pain in the region of the right parotid, which was hot, red, and swollen. No external application having brought relief, the author suspected a gouty element. However, he made the diagnosis of an abscess of dental origin, which would probably need surgical interference, but when he visited the patient two days later the parotid was still swollen, and the gout had invaded the left knee. Two months afterward M. d'Estrees saw the patient again at Contrevéville, and found that the gout had invaded successively the left parotid and the right knee. The patient felt well then, but complained of a very disagreeable salty taste in the mouth at the beginning of each meal. When examining the patient the author pressed upon the parotids, and at once excited the salty taste, which he subsequently demonstrated was produced by saliva loaded with urates, the epiphrenomenon of the gouty attack.

On another occasion he was called to see a patient with gouty parotiditis. In this case the attack in the parotid was preceded by an attack in the wrist of the same side. As external applications had been used without success, the author did not hesitate to use internal remedies, and prescribed tincture of fresh flowers of colchicum, fifty drops three times in twenty-four hours, and with each dose four grains of quinine sulphate. The treatment, he says, proved successful.

In another case gout began in the testicle, passed to the toe, and ended in the lung. In this case it was not, as in the cases described by Professor Potain, in the apex or at the base that the gouty congestion took place, but in the central part, and it did not extend over a surface of more than six centimetres across. Over and under this band of congested lung the respiratory murmur was perfectly normal.

What must a practitioner do, asks the author, if he meets with such a case of gout? In most cases, he says, if external applications are insufficient, he must use internal remedies. After he has calmed the attack he must procure the elimination of the uric acid and induce the patient to adhere to a selected diet and to strict hygiene.

The Early Signs of Locomotor Ataxia.—According to Professor Fournier, the first symptoms of locomotor ataxy may be classed as follows: (1) Sign of Westphal; (2) sign of Romberg; (3) the "stairs" sign; (4) crossing of the legs; (5) walking at the word of command; (6) standing on one leg.

(1) Westphal's sign is well known; it consists in the abolition of the patellar tendon reflex, and is present in two thirds of the cases.

(2) Romberg's sign can be thus appreciated: The eye is an indirect regulator of motion; it helps to correct deviations in walking and maintains the equilibrium. When a patient is suspected of incipient ataxy, it will often suffice to make him close his eyes when in the erect position to verify the diagnosis. In a few instances his body will oscillate, and if the malady is somewhat advanced he will be in danger of falling.

(3) The "stairs" symptom. One of the first and most constant symptoms of incipient locomotor ataxy is the difficulty with which the patient will descend stairs. If questioned closely on the subject he will say that at the very outset of his malady he was always afraid of falling when coming down stairs.

(4) The manner in which a patient crosses his legs is often significant. In the normal state a man when performing that act lifts one leg simply to the height necessary to pass it over the other, whereas in the affection under consideration he lifts it much higher than necessary, describing a large segment of a circle.

(5) Walking at the word of command. The patient seated is told to get up and walk instantly. After rising he will hesitate, as if he wanted to find his equilibrium before starting off. If while in motion he is told to stop short, his body, obeying the impulse, inclines forward as if about to situate, or, on the contrary, he jerks himself backward in order to resist the impulse forward.

(6) The patient is asked to stand on one leg, at first with his eyes open, afterward closed. Although man is not made for this position, yet he can balance himself pretty firmly for a little while. The ataxie will experience a great deal of difficulty, and will instinctively call to his aid his other foot so as not to fall. If his eyes are closed he will not be able to stand one instant, and if not held he would fall heavily to the ground. Such are the symptoms of incipient locomotor ataxy. They will not be all present frequently, but they should be all sought for in order to avoid an error which might have grave consequences.—Practitioiner.

Horse Meat and Sausages.—In an article entitled Chronique de l'Hygiène, which appeared in the Union médicale for February 16th, M. Jules Lecour calls attention to a report communicated by M. Nocard to the Paris sanitary authorities on the question of horse meat in sausages. M. Nocard had been empowered by the prefect of police to examine into a complaint put forward by a syndicate of the pork butchers of Paris, in which it was suggested that the vendors of sausages made from horse meat should be obliged to attach a special label to the sausages indicating their nature. At that time, says the
writer, there were no means by which horse meat could be distinguished from that of other animals, and M. Nocard, thinking that it was useless to lay down any measure that would receive no practical support, simply advised the prefect of police to redouble his care in the supervision of the abattoirs and of the inclosures where horses were slaughtered. Now, however, a simple and practical method has been discovered by M. Edelmann and M. Bruttigman by which this meat may be distin-
guished from that of other animals, even when it is mixed in very small quantities with the other meat.

This question, says M. Rochard, is an important one, for the consumption of horse meat is gradually increasing. In 1892, 16,483 horses, 206 donkeys, and 43 mules were slaughtered. All this meat is not sold in the 120 butcher shops which actually exist in Paris for the sale of horse meat alone, but the choice parts are sold, and the rest is cut up into sausage meat. This new industry is not attended with any danger in Paris, because the abattoirs, the shops, and the factories are under the constant supervision of competent veterinary surgeons; but in the suburbs and in the provinces such supervision exists in name only.

On the other hand, says M. Rochard, if sausages made from horse meat may be eaten in Paris without any danger arising from their consumption, the manufacturers who sell them with-out indicating their true nature deceive the public and carry on a dishonest competition with the pork butchers. For this rea-
son, says the writer, it is fortunate that such a practical and sure method has been discovered whereby this deception may be revealed.

This method consists in treating a bouillon which is obtained from the suspected product with iodized water. If it contains horse meat, no matter how small the quantity, a peculiar violaceous reddish-brown color will appear. The experiments made by M. Edelmann and M. Bruttigman have been tested and verified in M. Nocard's laboratory and under his personal supervision. The procedure is easy and does not call for a complicated outfit, the description of which may be found in M. No-
card's report to the board of health which appeared in the Compte-rendu des séances du Conseil for February, 1895. This report ends with the statement that the board of health voted, without discussion, that the manufacturers of sausages made from horse meat should attach a special label to the sausages indicating their true nature.

Influenza: Do Doctors Know Anything about it?—An evening contemporary assures its readers that notwithstanding the fact that we are now in the midst of the fifth successive an-nual epidemic of influenza doctors know little or nothing about it. There is, perhaps, some justification for this in the circum-
stance that a good many immature practitioners, who desire to pose as scientists in exsclasia, have assured the public on many occasions that science really can not say what influenza is. But now let us ask ourselves with the downrightness of mere com-
mon sense what it is that our profession really does know, and know thoroughly, about influenza. In the first place, we know the disease when we see it; we know also the injurious physiological and pathological changes it produces in the nervous system, the lungs, the liver, and other organs of the body; we know how, by prompt, early treatment, to reduce those changes to a minimum; and we know how to repair the dam-age done by those changes when the disease is brought to a termination. "But," it will be said, "if you claim to know all these things, you claim to know everything about influenza." No; we do not. We do not claim to know precisely what its cause is; nor do we profess to know entirely how to prevent it, but do we know what the cause of cancer is; or of typhoid fever; or of simple, or even of tubercular meningitis, and a hundred other things? Moreover, in the matter of prevention, can we prevent all other diseases of every kind except influenza? Can the lawyer, who thoroughly understands law, prevent crime? Can the theologian prevent sin? Can even the commercial man put an end to bankruptcy? Influenza has now been with us for five successive years. We can recognize it, we can treat it rationally and successfully, and to some extent we can pre-
vant it. Perhaps when Providence has endowed us with un-niscience and with almsightness as well, we may be able to entirely prevent the disease as well as to cure it. In the meantime a little "silence" might be "golden" on the part of the all-knowing lay journalist.—Hospital.

Nitroglycerin in the Treatment of Sciatica.—In the Lyon médical for February 24 there is an abstract of an article from the Semaine médicale, in which the author, Dr. P. M. Mikhalkine, of Nijni-Novgorod, remarks that he recently had occasion to become convinced of the powerful anitnarcotic properties of nitroglycerin in three cases of persistent sciatica that had been absolutely rebellious to the action of antipyrine, of acetanilide, of chloral hydrate, of the bromides, and of other analogus medicaments, as well as to the employment of re-
vulsives.

Under the influence of nitroglycerin two of the patients had been radically cured of their sciatica, and in the third case it had produced a considerable amelioration. It was adminis-
tered sometimes in a one-per-cent. alcoholic solution, of which three drops a day were taken, sometimes under the form of the following mixture: A one-per-cent. alcoholic solution of nitro-
glycerin, 75 grains; tincture of capsicum, 113 grains; distilled peppermint-water, 225 grains. From five to ten drops of this mixture are to be taken three times a day.

A New Hemostatic.—In the Lyon médical for February 17th there is an abstract of an article which appeared in the Therapeutische Wochenschrift for January 6th, in which the author, Dr. Hederich, of Heidelberg, recommends a new hem-
ostatic called ferrypyrine. This substance is a definite combina-
tion of iron perchloride and antipyrine under the form of a redish orange-colored powder which is easily soluble in cold water. It has several appreciable advantages over iron per-
chloride, and has neither its caustic qualities nor its bad taste; its hemostatic properties are, moreover, superior to those of the perchloride. In a case of profuse hemorrhage caused by a very vascular myxoma of the nasal cavity, the application of two tampons saturated with a twenty-per-cent. solution of ferrypyrine was sufficient to arrest the flow of blood completely. It may also be employed internally in doses of eight grains. Dr. Hederich thinks that it should be tried in cases of blemorrhagia in injections of a one-per-cent. or a one-and-a-half-per-cent. solution.

"Female" or Woman?—Dr. Howard A. Kelly writes as follows to the editor of the American Journal of Obstetrics: "A good friend with a fine English sense, who occasionally looks over my shoulder as I write, left this note pinned to one of my papers a few days ago. I think the fault common enough to be worth while correcting publicly. And as it is manifestly an error to which a gynecologist is more prone than other men, the correction ought to appear in The American Journal of Obstetrics: 'Take care not to use the word female as meaning 'a woman.' It is correct to speak of the female pelvic organs, but a female is not a woman. It is a cow, a mare, any animal of the female sex. It is old-fashioned English to call women females, and the expression is coarse in this sense.' "

AN OPERATION FOR THE RELIEF OF IMPERMEABLE OCCLUSION OF THE OESOPHAGUS OF FIVE YEARS' STANDING, WITH DILATATION BY A NEW METHOD.

By Dr. AUGUSTUS C. BERNAWS, M. R. C. S. Eng.,
Professor of Anatomy and Clinical Surgery
At the Marion Sims College of Medicine, St. Louis.

Reported by Dr. HOWARD CARTER,
First Assistant:
Senior Assistant to the St. Louis City Hospital, etc.

M. G., female, aged six years and a half, was brought to my office with the following history: When two years old she swallowed concentrated lye. The accident was discovered immediately after its occurrence and prompt medical assistance given; great oedema of the parts followed, and for a period of four days she was unable to draw the tongue into the mouth. When the local swelling and oedema had subsided, she was found to be unable to swallow. It appears that no attempt was made to prevent the formation of organic stricture until four months after the accident, the patient being nourished in the mean time through the rectum and by injection.

Numerous attempts were then made to pass bougies through the oesophagus, some under the influence of an anaesthetic and some without. A very limited number of these trials were successful, and on such occasions the withdrawal of the instrument was followed by the copious discharge of a purulent fluid. Once or twice, following the passage of the bougie, the patient had succeeded in swallowing a few drachms of water, the total quantity amounting to less than half a litre.

All further attempts to dilate or in any way to treat the stricture were then abandoned for a period of thirteen months, during which the patient was unable to nourish herself, and remained in a dwarfish condition. A list of the time would amount to only little more than half a litre. At the present time the patient is dwarf-like, and weighs only nineteen pounds, the limbs resembling those of a poorly nourished child of two years and a half; the facial expression is pinched and anxious, the intellect bright, with strongly marked individuality, and a predominating determination to "get cured."

The patient being chloroformed, an examination was made in the following manner: The fistulous opening in the epigastrum was first dilated by means of the index finger, which was introduced into the cardia orifice of the stomach for a distance of about four centimetres. The lower end of the oesophagus was found to be intact and the action of the sphincter perfect. Some destruction of the gastric mucosa had taken place, evidenced by the presence of cicatricial tissue. The stricture was too high to be located by the finger, which was withdrawn and a soft metal bougie introduced; this passed unopposed to a distance of twelve centimetres from the external opening in the epigastrum. A plaited-silk bougie was then introduced through the pharynx and into the oesophagus. The stricture was located about eighteen centimetres from the teeth, with a distance of seven centimetres of tortuous cicatricial tissue between its beginning and its end above the cardia. At this point the oesophagus is in close relation to the arch of the aorta, vena azygos, left common carotid artery, and thoracic duct. Further examination showed great distortion of the oesophagus, which had formed two diverticula on either side of the upper end of the stricture, the one to the right lying directly behind the manubrium sterni, the other over the apex of the left lung. The probable capacity of these two pockets amounted to thirty cubic centimetres.

Having arrived at this understanding of the case, we determined to perform an oesophagotomy as near to the beginning of the stricture as possible.

First Operation.—The bougie being removed, a metal male catheter was introduced through the pharynx and the oesophagus, and pushed forward and to the left of the trachea until the catheter could be distinctly felt immediately below the skin in the side of the neck. An incision was made, four centimetres in length, parallel to the inner border of the sterno-mastoid muscle, dividing the skin, fascia, platysma, connective tissue, and the anterior wall of the oesophagus, which was drawn forward and united to the integument by interrupted silk sutures. Owing to the debilitated condition of the patient, further procedure was postponed for a period of three weeks, during which time the oesophageal mucosa healed to the skin. For the first few days the pulse averaged 120, the temperature 100° F. Some difficulty was experienced from the constant flow of saliva over the wound, but no suppuration of any consequence followed. The sutures were removed on the seventh day.

When the wound was healed the nozzle of a syringe was introduced through the fistula in the neck and passed deeply toward the oesophagus; different attempts were made to inject water through the stricture, which, however, proved to be totally impermeable.

Second Operation.—Three weeks after the first operation, a second one was performed for the reduction of the stricture, which was now much more accessible, the patient's condition being as good as when first operated upon. When she had been chloroformed, the end of a soft rubber tube whose other extremity was attached to a Davidson's syringe was passed through the epigastric fistula into the gastric opening of the oesophagus. Pressure was applied to the bulb, but no water appeared at the fistulous opening in the neck. All attempts to inject water through the stricture from either side had utterly failed. A pillow was placed under the shoulders and the neck put upon the stretch.

The index finger was introduced into the oesophagus—through the opening in the neck, a soft metal bougie being at the same time passed into the lower portion through the cardiac orifice; at first the end of the bougie could not be felt by the examining finger, and much careful manipulation was necessary before it could be positively determined. The uncomfortable proximity of important vessels precluded the use of any cutting instrument. The bougie was then removed and its end cut to a trocar point with a scalpel and reinserted as before; when located, gentle manipulation was made against its point through the stricture by the index finger in the oesophagus, a rotary movement being simultaneously given to the bougie. In this manner the stricture was successfully perforated; the bougie passed upward to the opening in the neck, where a stout double silk ligature was attached to its end and drawn down through the oesophagus and out of the artificial opening in the stomach. Upon this ligature there was threaded through its lumen a Xelaton rubber catheter of an external diameter of 1.5 centimetres; this was drawn through the oesophagus until the upper end had entered the neck, and then pushed upward until the upper end could be seized in the pharynx and drawn forward out of the mouth; both ends of the catheter were now outside.

of the patient's body; they were sutured to the ligature, the ends of which were tied together.

I have made the following notes regarding the subsequent course of the case, which was placed exclusively in my hands: The patient rallied fairly well after the operation; the hemorrhage had been insignificant. Pulse remained 120 for several days; the temperature at no time exceeded 100° F. She became greatly emaciated. Liquid food was given at short intervals, and stimulants as indications demanded. Heat was kept applied constantly to the extremities, which were cold, especially the tip of the nose; the pupils remained dilated, and she manifested all the symptoms of profound shock. In order to allay the extreme nervousness and irritability antikamnia was given, and it acted promptly and satisfactorily in every instance. Some difficulty was experienced by the pressure of the catheter against the trachea, and I removed it from the mouth and drew its end through the opening in the neck. During convalescence food was introduced into the stomach through the epigastric fistula. On the seventh day the rubber catheter was reintroduced through the pharynx, and a plaited-silk Renvers funnel threaded upon and attached to the ligature passing through the catheter; their ends were brought in opposition and together they were drawn downward through the oesophagus, the catheter being entirely withdrawn and the funnel left in the oesophagus at the site of the stricture, its upper end remaining above it and its lower entering the stomach; the ends of the ligature were united on the outside as before. Both the artificial openings were then temporarily closed. The patient was given a glass of soda water, for which she had been constantly asking; the entire quantity was swallowed in the natural manner; this was soon followed by half a pint of water, and a few minutes later by half a pint of milk. This was the first food that had entered the stomach through the natural channel for three years. Pulse remained at 120; the pupils were widely dilated. On the fourteenth day I removed the Renvers funnel, the ligatures being left in situ. The general condition improved, the pulse falling to 85. She commenced swallowing through the natural channel. It was my intention to commence further dilatation at once, but owing to the non-arrival of suitable bougies dilatation was unavoidably delayed. At the end of a week the child was again brought to the office with the complaint that it could not swallow as well as at the time the tube was removed. She obstinately and persistently refused to open her mouth for the introduction of bougies, which were then introduced through the fistula in the neck. No. 12 (French scale) could be passed only with great difficulty.

The olive-bulbed whalebone bougies could not be passed in this manner. The stricture was then diluted every day for several days with plaited-silk urethral bougies until a No. 20 (French scale) was passed; this method caused so much discomfort that she surrendered unconditionally and opened her mouth. Olivary bougies ranging from 14 to 20 (French scale) were successfully passed through the stricture. I reintroduced a Renvers funnel, the largest that could be drawn through the stricture. This was removed on the third day, and three strands of heavy pedicle silk drawn through the oesophagus and gastric fistula. The end of one of these strands, which I shall designate A, was drawn through the opening in the neck and its ends tied together, forming a continuous cord.

The ends of another ligature were similarly tied; this I held in reserve in case of loss of either of the others. Upon the upper end of the remaining ligature I tied a loop two inches in length wherein could be attached any instrument with a similar loop which it might be necessary to draw through the oesophagus. The resistance to the passage of whalebone bougies necessitated some other method of dilatation. I therefore unscrewed the olivary bulbs from the whalebone probe and drilled a hole through the long diameter of each. Each bulb was threaded upon a stout ligature upon the end of which a six-centimetre loop was knotted. Two centimetres or so above each bulb I tied a knot sufficiently stout to prevent the ligature being drawn through.

The end of any loop can be passed through the oesophageal loop and the free end drawn through its own loop, thus uniting it to the main ligature by a reef knot.

A little vaseline was applied to the bulb and the knots, and the whole apparatus drawn through the stricture, ligature A being at the same time drawn tight.

I was able to pass the smaller sizes, but a No. 24 (French scale) could not be drawn through the stricture.

I then took each end of ligature A, which passed between the bulb and the edge of the stricture, and sawed backward and forward after Abbe's method until sufficient dilatation had taken place to permit the passage of the bulb. I then withdrew it and reintroduced a Renvers funnel.

The patient bore the see-sawing very badly, complaining of pain in the region of the stricture; the granulating edges of the gastric fistula bled very easily, and there was some irritation and dermatitis due to the escape of stomach contents.

The patient's condition is steadily improving; it is now two months since the first operation, and I can pass a bulb No. 30 (French scale), her appetite is good, and she has gained three pounds in weight.

The prognosis of oesophageal strictures caused by the swallowing of lye and other caustics, according to the experience of Professor A. C. Bernays, may be summed up as follows:

One third of all the patients die directly in consequence of the poison and the effects of the caustic. The second third are so severely affected that they die also after having undergone the most terrible sufferings from unsuccessful treatment, or as the result of perforations which cause mediastinitis, pleuritis, or peritonitis. Some die also of a putrid or septic bronchitis which leads to lobar pneumonia.
Many patients who have sustained only slight cauterizations from the swallowed alkali do not seek treatment for months or even years afterward.

Many cases are reported in which the patients got along quite well for years and only came to seek treatment when a piece of meat or other solid substance became lodged in the esophagus and caused obstruction.

About a third of all cases seem to be curable, but even in them the constant use of bongies is necessary to maintain a sufficient caliber in the esophagus. Von Hacker's table of a hundred cases proves that of fifty-five patients treated by esophagotomy, gastrostomy, or both, thirty-three were cured and twenty-two died, a mortality of forty per cent. Forty-five were treated with bongies only, and of these twenty were cured—i.e., kept alive—and twenty-five died, showing a mortality of fifty-five and a half per cent. There is no doubt that a large number who would otherwise die can be saved by operations.*

---

**TUBAL MOLE PREGNANCY.**

**WITH SOME REMARKS ON THE DIFFERENTIAL DIAGNOSIS OF ECTOPIC GESTATION.**

By HIRAM N. VINEBERG, M. D.,
INSTRUCTOR IN GYNECOLOGY
IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING GYNECOLOGIST TO MOUNT SINAI HOSPITAL Dispensary and TO THE MONTEFIORE HOME FOR CHRONIC INVALIDS.

The following case the writer thinks possesses considerable interest from a clinical standpoint and presents a specimen not frequently seen described even in these days, when the medical journals teem with reports of cases of ectopic gestation:

Mrs. A., aged thirty-two years, married ten years, has two children, the youngest one two years old. She had an early miscarriage four years ago, otherwise had enjoyed the best of health and never suffered from any pelvic symptoms. A week before the expected menses, which were to appear about the 1st of November, she was suddenly seized with pain in the region of the right kidney, the pain radiating along the course of the right ureter. This was attended with frequent micturition. Her physician, Dr. C. W. Bohmfalk, who saw her soon afterward, naturally supposed the attack to be due to the passage of a urinary calculus. This view was strengthened by the fact that the attack passed off in a couple of hours. Her anticipated menstruation set in at the expected time, but the flow lasted only for about a day, instead of three or four days as usual. Thinking she had taken cold, her physician applied some remedies, and the flow set in in a day or two, and, though it continued for three or four days, the patient felt it was not quite as profuse as formerly. About a week later the doctor was sent for again on account of another sudden seizure of pain in the right side of the abdomen. The pain lasted four hours and was accompanied by several fainting spells. Following this attack the patient had some temperature (101° to 102°) and more or less pain in the lower part of the abdomen. This condition of things continued until two or three days before I saw her in consultation on December 2, 1894. At that time there was no fever and comparatively little pain. On examination, I could not determine anything definite, owing to a very thick abdominal wall and a sensitive condition of the vaginal vault. The uterus was found slightly enlarged, in retroversion of the first degree, and was sensitive on pressure, as were also the parametria. I made the diagnosis of probable rupture of an early tubal gestation with the subsequent development of pelvic peritonitis. As no urgent symptoms were present and the diagnosis was uncertain, I advised the continuation of the palliative treatment and rest in bed. If at the end of three or four weeks the pelvic condition had not entirely cleared up an examination under narcosis was to be made. Exactly three weeks later, early in the morning of December 23d, the woman had another attack of pain, but this time in the left groin, and had one fainting spell after another. In the interval of these three weeks she seemed to be progressing favorably and had been free of fever and pain. Her physician gave an opiate to relieve the pain and in a few hours she was fairly comfortable. He at once recognized that an intraperitoneal hemorrhage had taken place, and requested that I should be called to see the case again. I saw her at 9 A.M. She then had a pinched appearance, but was not blanched. Had a pulse of 120 and an age temperature of 101°. The abdomen was very much distended and was universally tender. A bimanual examination was now even more unsatisfactory than at the first time. We agreed upon immediate operation and the patient was conveyed to the Post-graduate Hospital, where I operated on her at 3 P.M. of the same day.

When the abdomen was opened a very unpromising state of things presented itself. The omentum was adherent to the symphysis pubis and walls of the pelvis and had to be ligated in sections and resected. The intestines were matted together by fairly firm adhesions. After careful separation of the adhesions with the fingers, I finally opened a fair-sized cavity partly filled with liquid blood and partly with blood clots of various degrees of organization. Some were dark and soft, others were whitish, very firm, closely adherent to the walls of the cavity, and had to be cut away with scissors. After cleaning out the cavity my fingers could reach the uterus in the posterior part of the pelvis. On the right side of the uterus lay an irregular mass of the size of a California pear imbedded in firm

---

* Von Hacker was the first to propose the method of passing a thread through the stricture and out through an artificial gastric opening, thus making an endless probe (Wiener med. Wochenschrif, 1866, Nos. 31 and 32).
adhesions. It was with great difficulty that the tumor was enucleated from its bed, ligated, and cut off. There was now a large, irregular cavity, presenting a dark, uzy appearance, and from its bottom there was considerable oozing of blood. The cavity was packed with a Mikuliez tamponade of iodiform gauze. The abdomen was closed in the usual way, excepting at the lower part, which was occupied by the strips of iodiform gauze. The patient made a smooth and satisfactory recovery.

The removed mass was found to consist of the dilated tube and the ovary hanging from it. On longitudinal section the tubal walls were found to be quite thin, the whole tubal cavity filled by a firm pinkish mass, which was quite firmly adherent to the interior of the tubal wall for its greatest part. The interior of this pinkish substance displayed a small, irregular cavity with several projections. Hanging from the side of the cavity, near the distal end, was a yellowish-white strand not unlike the blighted ovum seen in early cases of uterine mole. The lining of the small cavity was smooth and glistening. The under surface of the tumor was rough and uneven where it had been adherent to the pelvic floor. Several artificial tears in the tubal wall were produced by enucleating the tumor from its bed. Consequently the point of spontaneous rupture could not be definitely located.

The points of clinical interest are:
1. The misleading character of the first attack.
2. The early hemorrhage into the decidual membranes; this having probably taken place as early as the second or third week of gestation.
3. The recurrence after the death of the ovum of two attacks of intraperitoneal hemorrhage at an interval of three and six weeks respectively.
4. The occurrence of ectopic gestation in a woman who presumably had healthy pelvic organs and who had given birth to a child at full term only two years before.

As we all know, the diagnosis of many cases of ectopic gestation offers no difficulties. There is a missed period, then irregular hemorrhages from the uterus, usually attended with sudden attacks of great pain, and on examination a small semi-elastic tumor, shaped like an egg, but flattened in form, sensitive to pressure, can be felt closely attached to one or other side of the uterus, or it may be situated behind the uterus, and in some reported cases it has even been found in front of the uterus.

Another class of cases easily recognized is when a woman has passed one or more periods, believes herself to be pregnant in the natural way, and is suddenly taken with sharp pain and symptoms of acute anemia and collapse. Examination will reveal a slightly enlarged uterus and a bogginess in Douglas's cul-de-sac.

These are cases which are not uncommon and in which there is little likelihood of making a wrong diagnosis. But occasionally, and I may even say frequently, cases are met with which puzzle the most experienced observer and the most skilful diagnostician. First in order of importance are cases of intra-uterine gestation which may be mistaken for extra-uterine. Occasionally we meet with a gravid uterus which, instead of enlarging uniformly, enlarges more at one part, thus giving rise to bulging and to the physical signs to a greater or less degree of a tumor attached to the uterus. Inasmuch as this phenomenon is more likely to occur in chronic metritis and in cases of adhesions, in which there is a tendency to abortion, the mistake in making the diagnosis of extra-uterine gestation is the more readily committed. A case in point is the following:

A young married woman had passed her period for ten weeks, when she began to have pain in the lower part of the abdomen and slight hemorrhages. On examination I found a uterus the size of a gravid organ at ten weeks. The enlargement, however, was not uniform, there being a distinct bulging of the posterior wall which made the impression of a tumor the size of a hen's egg. Without taking any credit to myself I must frankly say the idea of ectopic gestation did not occur to me. I sent her to a well-known colleague, who is an excellent diagnostician, for the purpose of demonstration to a class of students.

He diagnosed ectopic gestation. In a week afterward I was sent for, and on my arrival found the ovum with its envelopes lying in the upper part of the cervix. I removed it easily with my fingers. It was simply a case of intra-uterine gestation which had aborited at about the eleventh week from chronic metritis.

In my dispensary practice, where I examine during the year from two hundred and fifty to three hundred cases of pregnancy at various periods, it is not uncommon for me to meet with these cases of irregular enlargement of the uterine, simulating to a greater or less degree the physical signs of an ectopic gestation. The points of difference, however, are:
1. The apparent tumor is not so well defined as that of ectopic gestation.
2. It is not so sensitive as the tumor of ectopic gestation is likely to be.

I wish to lay special stress upon this cause of error in diagnosis, as I have not seen it stated anywhere before. I am certain many cases recorded as interstitial uterine preg-
VINEBERG: TUBAL MOLE PREGNANCY.

Dr. M. McLean, at a recent meeting of the New York Obstetrical Society, related a very interesting case which forcibly illustrated this point in diagnosis. The patient had been four months pregnant. She had uterine hemorrhages, attended with severe pains in the abdomen, fever, and a rapid pulse. On examination, a mass the size of the gravid uterus at the sixteenth week was found to the right of what was supposed to be the non-gravid uterus slightly enlarged. A diagnosis of ectopic gestation was made. On opening the abdomen it was found that the larger mass on the right side was part of the gravid uterus, which had enlarged irregularly and given rise to the physical signs of an independent tumor. This part of the uterus was adherent to the pelvis. The adhesions were broken up, and the uterine gestation went on uninterruptedly.

The next condition of intra-uterine gestation which may be mistaken for ectopic is retroflexion with elongation of the cervix. The enlarged body lies low down in Douglas's cul-de-sac and the elongated cervix gives rise to the impression that it is the uterus lying in front of the tumor. I recall a case of the kind about six years ago which deceived many well-known specialists. At first the so-called tumor in Douglas's space was looked upon as an ovarian cyst.

The patient was about thirty years of age, married over two years, and had been sterile. The accompanying amenorrhea did not excite suspicion, as that symptom frequently attends an ovarian cyst. A sound had frequently been passed into what was supposed to be the uterus, and it would enter to a distance of two inches and a half in a forward direction. The tumor kept on increasing in size, and the woman complained of pain and discomfort in the lower part of the abdomen. I lost sight of her then for some months, when one night I was sent for. On reaching the house I found her in bed and suffering from what I at once recognized as labor pains. The abdomen was the size of that of a gravid woman at full term. On examination, I again found the uterus-like body lying forward, and, though the pains were severe and had lasted several hours, the cervix was long and undilatable. I then supposed I had to do with an ectopic gestation at full term, and sent for the late Dr. James B. Hunter to consult with. After examining the patient, Dr. Hunter felt confident that it was a case of ectopic gestation at full term, advising me to remain with the patient overnight until she could be transferred to the Woman's Hospital in the morning. To subdue the pain I gave, with his advice, hypodermics of morphia, but in spite of these the pain continued. Toward morning the cervix began to open up, and in due time the woman was delivered of a good-sized female child.

Dr. Hunter at the time related to me a similar case—that of the daughter of a well-known physician of this city. The woman was operated upon, and the error only then recognized. Since then I have seen a number of cases of gestation in retroflexed uteri, which I might have mistaken for ectopic gestation had I not retained a vivid impression of the foregoing case.

The only author I have been able to find who lays par-
ticular stress upon this point is Fritsch.* He says: "Very difficult would it be to distinguish it [tubal pregnancy] from a retroflexed gravid uterus. In the latter case the uterus is strikingly soft, while the cervix may be so hard and elongated that it is taken for the whole uterus, and the soft body in Douglas's space for the extra-uterine sac. Whether such a case has been operated upon before the error was recognized I do not know, but my own experience convinces me that in several cases such a doubt could only be solved by a thorough examination under narcosis."

A third condition which might lead to error is pregnancy in one horn of a uterus bicornis.

Last winter a woman from Long Branch, N. J., came to the dispensary with the history of having passed her period twelve weeks, when she began to have pain in the right side of the abdomen and had irregular hemorrhages. The woman was of a low order of intelligence, and all that could be gained from her was the foregoing, and that she was married eleven months, and had had a miscarriage at three months, eight months before. On examination, a spherical tumor, the size of a gravid uterus at the twelfth week, was found in the right side of the pelvis.

On the left side of the tumor was a body the shape and size of a normal non-gravid uterus. I at first thought I had to deal with a case of ectopic gestation, but some obscure points led me to the determination of keeping her under observation for a few days. During this time, after repeated and thorough examinations, I made out a uterine bicornis with pregnancy in the right horn. The two horns were widely separated, and were united only at the cervix. This conclusion was only reached after a sound had been passed through the common cervix into the horn on the left side for a distance of three inches. I learned afterward that the woman aborted a couple of weeks later.

A fourth condition which may give rise to a mistaken diagnosis is when there are symptoms of threatened abortion in a gravid uterus of early date, and on examination a tumor is found on one or other side of the uterus. Such a mistake, however, is of no great moment, for the tumor—let it be an ovarian cyst (as in a recent case of mine), or an ovarian or tubal abscess—is an indication for operative interference. The writer makes no pretense in the foregoing remarks of covering all the ground of errors in the differential diagnosis of ectopic gestation. He merely wishes to draw the attention of the general practitioner, who usually sees these cases first, to some of the more important conditions that may lead to error, and which have not received sufficient recognition heretofore.

Note.—After the foregoing had been put into type the following was received from Dr. Thomas S. Cullen, of the Johns Hopkins University, Baltimore:

"The specimen consists of a dilated Fallopian tube and of an ovary.

'"Description of Alcoholic Specimen.—The tube is five millimetres in diameter at its uterine extremity, but, after passing outward one centimetre, it suddenly dilates, becoming three centimetres in diameter. It then gradually diminishes in size, and six centimetres from its uterine end is only one centimetre and a half in thickness. The fimbriated extremity is patent, but some of its folds are adherent to the ovary. Along the convex upper surface of the tube is a rupture five centimetres in length and three in breadth. Projecting through this rent is a"

reddish mass. The surface of the tube is covered by a few delicate adhesions. Its walls average one millimetre in thickness. The inner surface of the tube is smooth and glistening, and in a few places delicate folds of the mucosa are seen running parallel to the long axis of the tube. The reddish mass contained in the tube is six centimetres in length, four in breadth, and three and a half in its antero-posterior diameter. On section, its center is found to contain an irregular cavity two centimetres and a half long and one centimetre and a half in breadth. The walls of this are smooth and glistening, and are lined by a very delicate membrane. The lower surface of the mass presents a ragged opening nine millimetres in diameter. Around the margins of this opening are delicate slivers of tissue. The ovary is 3.5 x 2.5 x 2.5 centimetres in its various diameters, is covered by numerous adhesions, and is soft and yielding.

"Histologically.—The tube, at the point where it begins to enlarge, is covered by numerous non-vascular adhesions. The muscular coat is swollen, the nuclei of some of its fibers being of twice their normal size. The tissue between the muscle bundles is markedly infiltrated by lymphoid cells. The endothelium of the arteries of the muscular coat is swollen and has in some places undergone proliferation. The irregularly round or oval villi, or the outer surface of the membrane is covered by two rows of cells which are somewhat flattened and have oval or spindle-shaped nuclei. In the vicinity of the villi are a few so-called placental giant cells. In the center of this clot is the cavity lined by the delicate membrane. The inner surface of this membrane is covered by one layer of somewhat flattened cells which are oval or round. The membrane itself is composed of a hyaline matrix containing a moderate number of cells whose nuclei are irregularly round or oval. The outer surface of the membrane is covered by two distinct layers of cells; the one nearest the membrane has spindle-shaped or oval nuclei, the outer one consists of protoplasm everywhere presenting little knoblike outgrowths which contain masses of oval, deeply staining nuclei scattered irregularly throughout them. In some places these knoblike masses have been cut off and form the so-called placental giant cells. This membrane is the chorion. The ovary is covered by numerous non-vascular adhesions. Its stroma contains several Graafian follicles and corpora fibrosa.

"Diagnosis.—Tubal pregnancy. Slight peri-ophoritis. No trace of the fetus could be found."

127 East Sixty-first Street.

The Separated Milk Game.—At Westminster, on September 27th, the St. George's (Hanover Square) Vestry by summons, prosecuted Tom Felie Stevens, of 52 College Place, Chelsea, before Mr. de Rutzen, for selling milk from which the cream had been abstracted to the extent of thirty-five per cent. Mr. Herriott, the vestry's inspector, bought a pint of milk for a penny three farthings from a man in the service of the defendant out with a barrow. After the purchase was completed the salesman drew the inspector's attention to the fact of a label pasted on the barrow with the words thereon, "Pure separated milk." He also said that new milk could not be expected for the price. Mr. de Rutzen told the defendant that he had not brought himself within the meaning of a particular case decided, and fined him 4s., and 12s. 6d. costs.—Food and Sanitation.

THE MECHANICAL TREATMENT OF POTT'S DISEASE OF THE SPINE, IN THE SUBACUTE OR CONVALESCENT STAGE.*

BY JOHN C. SCHAPPS, M.D.,

SURGEON TO THE DEPARTMENT OF ORTHOPEDIC SURGERY AND DISEASES OF THE JOINTS, ST. MARTIN'S HOSPITAL, BROOKLYN, N. Y.

Physiological rest of the spine is possible only in the recumbent position, and during the acute or soft stage of Pott's disease this position, with adjusted pressure and, if necessary, traction, should be uninterruptedly maintained. But when for several months the deformity has shown no increase, the patient has eaten and slept well, enjoyed good general health, and, most important, the spine outside the diseased area has regained its flexibility, the convalescent stage may be considered as entered upon, and recumbency may be gradually and carefully exchanged for the upright position. This transition involves the bearing of weight, and that frequently at a mechanical disadvantage because of deformity. It involves, also, a constant subjection to adverse muscular action and external traumaism. It is therefore a period of great danger, and it is well for the friends of the patient to understand that, however long it may have been delayed, the upright position is always an experiment, and that it may be advisable at any time to return to recumbency.

If, on the flexible back of a child, the distance along the spine from the base of the skull to the sacrum be measured in the upright and in the flexed positions, it will be found that in the latter it is longer by several inches. This increase represents the total separation of the tips of the spinous processes. So far as antero-posterior motion is concerned the spine may be regarded as a series of short bones hinged together. The spinal cord is secured in its canal throughout the whole length by the nerves. There is no slack in the lower nerves to be taken up by traction on the cord, but, on the contrary, they extend from their origins directly downward before emerging from the canal. If the axis of motion between these short bones were behind or in front of the cord the bones would be separated and the cord subjected to dangerous stretching during either posterior or anterior flexion. It is probable, therefore, that the axes of antero-posterior motion pass transversely through the neural canal. It is a matter of common observation that in Pott's disease symptoms denoting lesion of the cord or its membranes have no fixed relation to the aetenuity or amount of deformity; and pathological specimens show that whether the kyphoses be more or less angular, the caliber of the canal is not usually affected. The axes of deformity must therefore be the same as those of normal antero-posterior motion. The lateral deviation which may have been observed in the acute stage is to be regarded as an irritative muscular symptom rather than a unilateral loss of bone, and is gradually

* Read before the Orthopedic Section of the New York Academy of Medicine, January 18, 1895.
In the application of mechanical support to the upright spine, if we could grasp the spine directly we would immobilize it and apply forward pressure to the real or prospective kyphos; backward pressure to the parts above and below, with traction and counter-traction. But as we can not, it is necessary to study the nature and relations of the parts through which our mechanical remedies must reach the spine. The relative merits of traction and leverage have been frequently discussed. It is, however, evident that force or support, whether applied in a horizontal direction as leverage or vertically as traction, can act on the spine only by a motion the reverse of that of the deformity and around the same axes. And until this curvilinear motion has reached its limit traction can not tend to distract. Even then the tractive force can not be equal to the weight of the parts above the diseased area plus the resilient force of the ligaments and muscles binding the vertebrae together, for this necessitates a pressure greater than the skin can bear. It is then simply a question of utilizing every square inch of available body surface for the application of both leverage and traction. Let us consider the areas of possible application for remedial force or support. Pressure forward is to be applied to the kyphos, or at the situation of a possible kyphos. Pressure backward may be applied to the forehead, chin, thorax, shoulders, and anterior edges of the iliac bones. Pressure upward, or traction, may be exerted on the chin, back of the head, and under the shoulders. Pressure downward, or counter-traction, is applicable to the shoulders, iliac crests, and the projecting gluteal muscles. The question of pressure upon the abdomen made with a view to spinal support or correction demands careful consideration. By virtue of the arrangement of layers of the abdominal wall it does, under conditions of muscular tension, have a certain degree of cylindrical firmness. When there is a projection forward of the lumbar spine and abdomen accompanying a dorsal kyphos, if the lumbar spine is very flexible it may be somewhat straightened by backward pressure upon the abdomen; and abdominal pressure may serve also in extreme deformity to supply, through the viscera, some degree of internal support for the chest wall and also for the spine. But the abdomen is like an air cushion in front of the spine, and pressure applied to it is not transmitted in a straight line, but is exerted, more or less equally, in every direction. Internal tension in the thoracic-abdominal cavity is necessarily exerted somewhat upon the diseased spine, which is a weak spot in the parietes, and tends thus to increase its pressure against the external support. And as instrumental support is limited entirely by the pressure-tolerance of the skin, internal tension becomes a consideration. But abdominal pressure is far more serious, because of its interference with the circulation and respiration, and its tendency to produce visceral displacements and hernia.

In cervical or high dorsal disease the trunk grasped as a whole, and the head, respectively afford good means for the application of remedial force or support, both vertical and antero-posterior. The shoulders, although indirectly and loosely attached to the spine, may be made to sustain to some extent the weight of the parts above them. Axillary support from the pelvis is also of some relief to the spine below the shoulders.

In mid or upper dorsal disease a very prominent part of the deformity is that of the chest known as pigeon breast. Its mechanism is probably this: The upper ribs are more horizontal than the lower, which incline downward from the spine. As the vertebrae above the apex of the kyphos drop down, they tilt downward the upper ribs, which in turn tend to carry down the upper end of the sternum. At the same time the lower ribs are tilted upward and their normally greater inclination downward with their length causes the lower end of the sternum to be carried forward. Thus the forward inclination of the sternum is increased, and as this bone is fixed at its ends the front extremities of the intervening ribs are also fixed. Projection backward of the vertebrae serves to draw on these ribs so that the backward projection of the latter at their angles, or the forward projection of the spine into the chest, is diminished and the two sides of the back become like the sloping sides of a roof, of which the spine forms a curved ridgepole. The chest is elongated in the posterior direction and contracted laterally. This change is usually most marked in the lowest part. When, as the result of great spinal deformity, the entire trunk is considerably shortened, the chest sinks down upon the abdomen. I have watched the respiration in such a case and observed that as the diaphragm contracted the central part resting on the abdominal organs became the fixed point, and the contraction raised the chest and head. Under such circumstances the muscular and tendinous structures connecting the lower front of the chest to the front of the pelvis are relaxed and no longer serve to tie down the sternum. The posterior surface of this bone and the adjacent costal cartilages are now resting upon the abdominal contents, and this weight of the superincumbent parts tends to increase the abnormal forward inclination of the sternum. When the upper dorsal spine is inclined forward, the head, to preserve the equilibrium, is drawn backward, and thus the deformity is made more conspicuous.

In dorsal or lumbar disease the mechanical problem is to apply to the trunk itself forces acting in different directions; and as backward pressure can reach the spine only through the medium of the chest and pelvis, the foregoing analysis of thoracic deformity should be kept in mind; for, by a direct backward pressure on the sternum with forward pressure upon the kyphos, the lower ribs are pressed downward in front, and through the ribs as levers a powerful corrective force is brought to bear upon the spinal deformity.

The theory upon which pressure is made on the kyphos has been that of keeping the diseased part as nearly as may be in its natural relations with the parts above and below. But in dorsal disease it is evidently important to keep it in its normal relations also with the parts on either side. This is possible only by the use of direct

---

backward counter-pressure applied to the front of the chest. Such pressure has no injurious effect upon the thoracic respiration, as respiratory movements of the ribs are chiefly performed by a rotatory movement around a straight line uniting the vertebral and sternal extremities; and in so far as the pressure tends to shorten this line and restore the convexity of the ribs, it increases the respiratory function. The evils of circumferential pressure applied to the trunk are self-evident. Besides interfering with respiration and producing internal tension with its consequent mentioned, it induces a permanent contraction of the lower thorax and a small substernal angle. This has been held by such eminent authority as Laennec to be a predisposing condition to phthisis pulmonalis. In a patient with a tuberculous bone lesion it is a very serious matter.

In the treatment of lumbar disease no new principle is involved. It is still a question of exerting anterior pressure on the kyphos, with posterior pressure above and below. Here the superior mass is so great as to make traction of little or no service.

The apparatus which I employ to meet these mechanical indications is here presented. Posteriorly it is the Taylor brace (Fig. 1) with some unessential modifications, not my own, made with a view to simplifying it. Instead, however, of securing it to the trunk by a soft apron, which exerts a large amount of circumferential pressure and a minimum of posterior pull, I apply a rigid support in front (Fig. 2), and the trunk is sandwiched between two braces, which are drawn directly toward each other. For the reasons given above I have avoided, as a rule, abdominal pressure. An additional reason for leaving the abdomen uncovered in front is that distention from food, gas, etc., would tend to lift the brace from those parts where its pressure is most efficient. Commencing with the lower end, the anterior brace presents a steel band passing across the abdomen and well around the sides of the pelvis, as low as is possible without its being displaced by the thighs when the patient sits. The anterior-superior spines are protected by thick pads of kersey and leather, and the central part of the band is arched so as to prevent pressure on the abdomen. It is essential that the band should bend sharply around the front edges of the ilia and fit tightly against the sides of the pelvis for about an inch. By means of straps at the ends of the band it is connected with the hip band of the posterior brace, and the pelvis is literally clamped between the two bands, which nearly meet at the sides. At the location of the anterior-superior spines two flat rivets are riveted at right angles, or, if the abdomen is very protuberant, they are directed outward from the lower band. The curving of this band permits the uprights to be approximated above. They extend upward and inward along the abdomen and chest to the infraclavicular spaces. At the level of the axillae they are crossed by a flat bar, which passes across the front of the chest and nearly through the axillae at each end. No. 16 spring steel is a good material for the construction of all parts. Near the level of the chest band three holes, drilled three eights or half an inch apart, will save trouble in placing the band, which should be fastened by iron rivets. The abdominal band should be an inch, the others half an inch, wide. These dimensions are for children. It will be more convenient to have the separate parts covered with leather and then fastened together. In measuring one is very apt to locate the chest band too high, as well as to make the whole front brace too tall. It is very instructive to note how far the anterior chest wall will, notwithstanding all possible pressure, sag down in the upright position. It demonstrates strikingly the mechanical advantages of the supine position with reference to traction. At the upper ends of the uprights are straps which pass over the shoulders to buckles on the shoulder pieces of the posterior brace, and from the ends of the chest bands straps running backward buckle to the cross-piece of the brace. This cross-piece extends to the posterior edges of the axillae. Behind the upper part of the apparatus is a stiff leather perforated chest piece, which is secured to the uprights and covers the front of the thorax as far down as the ensiform cartilage. In some cases I have supplemented this by bands of aluminum or leather passing from upright to upright across the abdomen, but, for reasons given, it seems, as a rule, best to leave the abdomen free. Near the lower ends of the uprights are web straps (commonly padded) which extend over the crests of the pelvis to the buckles on the spinal uprights behind. These and the hip band of the posterior brace afford all the vertical support anatomically possible. The ends of the bar passing through the axillae may be padded as axillary crutches. Or from the ends of the shoulder pieces the regular round, padded shoulder straps of the Taylor brace may pass through the axillae and back to a second cross-piece placed just below the first. The perforated chest-piece can be made to fit accurately by bandaging it while wet to the chest, oiled silk being interposed. In high dorsal and cervical cases the head support which I prefer is Taylor's, without the ball-and-socket
joint, the slipping of which is a continual annoyance. In its place I use a pivot, flattened below, to slide in a keeper fastened to the uprights. This pivot has a soft neck which may be bent easily in any direction. This is, I believe, the original device of Dr. C. F. Taylor. Thus constructed this combination of anterior and posterior braces constitutes a skeleton support, to which parts may be added to meet the individual requirements of a case or the special views of the surgeon. If a greater area of lateral support be required it may be secured by a series of straps from the anterior to the posterior uprights. I think, however, that in Potter's disease lateral curvature from muscular spasm is best treated by recumbency.

It is claimed for this combination:

1. That all the available space is utilized for the application of force, both of leverage and traction.

2. The force applied for the purpose of leverage is expended entirely in the antero-posterior direction.

3. The anterior and posterior braces nearly meeting at the sides, lateral support is amply provided in every case where recumbency is not needed.

4. The grasp of the trunk, as a whole, for the purpose of counter traction in disease of the upper spine is as complete as possible.

5. There is an absence of circumferential pressure, so that the abdominal, diaphragmatic, and lateral thoracic movements are unobstructed.

6. The directly backward pressure of the leather apron serves:

(a) To antagonize any tendency to an anterior protrusion of the chest.
(b) To exert through the ribs a leverage upon the diseased vertebræ.
(c) To preserve or restore the normal posterior-lateral curve of the ribs, and so enhance the respiratory functions, and to keep the diseased spine in normal relations to the posterior chest wall on either side.

7. The back or any other part of the trunk can be at any time readily inspected.

8. The apparatus can be easily modified and pressure on any part accurately adjusted.

9. It is so simple that any blacksmith can make it.

10. The functions of the skin as a respiratory organ are respected.

I use also rubber heels in conjunction with this apparatus to minimize concussion, diminish direct traumatism, and save reflex muscular action.

The question, "How long should a brace be worn?" is difficult to answer, even in each particular case. On the one hand, increase of deformity, or the evidence by face, attitude, or gait that the patient is not getting the proper support, should be the indication for a return to the recumbent position.* On the other hand, the continued absence of symptoms of active disease, the general activity and well-being of the patient, afford the best possible reasons for the watchful and gradual removal of support.

---

**THE HISTORY OF THE TREATMENT OF SPONDYLITIS AND SCOLIOSIS BY PARTIAL SUSPENSION AND RETENTION BY MEANS OF PLASTER-OF-PARIS BANDAGES, Together with the Present Status of this Plan of Treatment before the Profession of the World.**

By Lewis A. Sayre, M. D.

(Concluded from page 320.)

Henry M. Sherman, San Francisco: "I am very glad indeed to submit to you, my old master in my art, my experiences and conclusions in regard to the plaster-of-Parris jacket, and to let such of them as merit it reach the profession through your paper.

"I advance the following propositions:

1. In cases of vertebral tuberculosis, when the lesion is below the ninth dorsal vertebra, the treatment by 'partial suspension and retention by plaster-of-Parris bandages' is incomparably the best, always excepting those cases in which for special and obvious reasons—theuria, abscess, sinus, etc.—no plan which contemplates the rigid enveloping of the body can be allowed. I am sure this contention can be made, though I have been obliged to modify my earlier views of the work of a jacket both as a splint and as a support.

2. In cases of vertebral tuberculosis, when the lesion involves the eighth and ninth dorsal vertebrae, the choice lies between the jacket and a brace, the former being suitable for milder cases, and those in which a compensatory lordosis could be easily developed both above and below the kyphos.

3. In cases of vertebral tuberculosis, in which the lesion is above the eighth dorsal vertebra, the plan of treatment should include carriage of the head by apparatus, and in all such cases the supporting point of the mechanism is the pelvis, which is embraced by a jacket of plaster of Paris or a pelvic belt of leather. For the support and carriage of the head I prefer the steel fork and aluminum chin collar which I have described.

4. In cases of scoliosis the plaster-of-Parris jacket as a rigid all-embracing splint on the trunk is the most satisfactory means to hold and make permanent the correction gained by gymnastics, forcible correction of deformity, etc.; but its function is purely that of a splint—i.e., retention, not correction—and, like all splints, muscular weakness of the muscles corrected and aided by it results from its too exclusive and too prolonged use. I am myself working with a fair amount of success on the lines of these proportions. Of course, I can not claim them to be universally applicable, and have myself exceptions to them in my practice, but they are a more than good set of working rules."

R. H. Plummer, San Francisco: "My experience in this method of treatment reaches through a period of fifteen years, during which time I have applied it not only in private practice, but in Cooper Medical College Dispensary as well, and it affords me great pleasure at this time to testify to you in no uncertain terms my appreciation of the merits of the method of treatment. . . . That the method has not given unqualified satisfaction to all who have attempted to use it goes without saying. Failures arise from various causes, as improperly selected cases (incurable); improper materials used, as unsuitable shirts; unskilful application of the bandages; and a general injudicious management of the case as to exercise, etc. All these deficiencies may be summed up in four words—viz., 'ignorance of the method.' If all who essay to use it would first familiarize themselves with your writings upon the subject, and especially if they could avail themselves of the benefit of your personal instruction as to details, etc., the method would not suffer at
their hands, and their patients would invoke blessings on their lives.

L. C. Lane, San Francisco: "I fully approve of your method of suspension and retention by plaster-of-Paris bandages in the treatment of spondylitis and scoliosis. I regard this plan of treatment as one of the most important additions made to surgery during the present century."

S. H. Pinkerton, Salt Lake City: "In the treatment of spondylitis I consider the partial suspension and a properly applied plaster-of-Paris jacket (with its modifications) superior to all mechanical appliances.

In scoliosis I have had very good results with a removable plaster of-Paris jacket (or corset) together with gymnastics."

William E. Wirt, Cleveland: "It has been my experience as an orthopaedic surgeon to have applied at least two hundred, possibly double that number, of plaster-of-Paris jackets to cases of Pott's disease. I consider this jacket a great boon to those unfortunate children, especially when the disease occurs among the poor and ignorant—in fact, nothing can take its place. Among the wealthy and intelligent, and more especially those whom we may trust to carry out directions, I have found a modified Beely corset to be more satisfactory. In certain cases of Pott's disease, where I had ordered a spinal brace, I have found that no amount of fitting and adjusting would make it comfortable to the patient, and in such cases would have to return to plaster jacket or felt corset.

In scoliosis I do not favor the plaster jacket as a measure of treatment, but I simply use it as a means of getting a mold which I still further improve in shape (over that gained by suspension) before molding upon it a felt corset."

S. A. Wright, Manchester: "In reply to your question:

1. I have never used any fixed apparatus for scoliosis.

2. For carries of the mid and lower dorsal and lumbar region I have always used, and do still use, Sayre's jacket largely, but not in cases where there is an abscess, nor in cases where the disease includes the upper dorsal region. I am not strongly impressed with the value of any form of jury-mast, and where the jacket is inapplicable I prefer bed or a metal spine spring."

C. H. Golding-Bird, London: "Re Scoliosis: (a) Plaster Bandages.—After a continued trial of the bandages in these cases I abandoned them; not that they did not at first give the greatest support, keep the spine straighter, allow of the chest being kept (in bad cases) more expanded, but because I found these results to be but temporary. In spite of the exercise with the tripod I did not find that the musculature of the trunk improved to the degree requisite for the patient's maintenance, as the improved position is to be obtained rather by the best possible development of the muscles (whereby the wearing and wearying muscle pain attendant on these cases is abolished and the patient rendered able to be about with comfort) and not by the most perfectly shaped back, if the muscle tone can not at the same time be maintained to the full. I less and less, therefore, use supports, preferring to throw the onus of maintaining an improved position on the patient's own muscles, being careful to give alternately with causticsthenics such rest as in each case is needful.

Where patients are already cripples and a lifelong support is necessary, then doubtless the jacket gives the maximum of comfort; but in practice I have found, in every station of life, that where such support is requisite the patient after a time prefers an apparatus (felt or otherwise) that can be removed for toilet purposes to the plaster that is immovable and that has to be reapplied at stated intervals, even at a loss of some of the support that the bandage gives.

"Re Scoliosis: (b) The Tripod Exercise.—This can hardly be improved upon; and it remains the type of what technical calisthenics in these cases should be.

With due attention to the patient's environment of place and habit, the muscles soon develop and harden under its proper use; and it brings the greatest number of trunk muscles into play at a given time, with a minimum of fatigue; in this surpassing other and more popular forms of exercise.

Even in confirmed scoliotic cripples, I have seen the daily expansion of the chest by the tripod exercise improve the heart's action and materially aid in the restoration of the patient's health, by mechanically permitting the better oxygenation of the blood and the freer action of the heart.

"I consider it of more value than the plaster jacket in the Sayre method of treating scoliosis.

"Re Spondylitis: (a) The Plaster Jacket.—In spondylitis the jacket fulfills all that its inventor claimed for it, allowing patients to be about and in the open air instead of being kept always on their backs; and they recover, where the jacket is efficiently and sufficiently often applied, with as slight deformity as though they had been kept lying down all the time.

"I know of no disability attending the employment of it important enough to prevent its universal application; but at the same time, I have never known any treatment introduced into surgery that was less understood, or about which less trouble was taken to understand it practically.

While I still employ it in public practice, it is many years since I did so in private. The agitations of those who had vested interests in spinal cases, and the prejudice of the public against an appliance that could not be removed for the bath, in a few years caused it to fall into disrepute, and save for hospital cases I do not think it is ever now employed.

The public refused to regard the benefit the jacket afforded as in any way weighing against any slight disagreeableness it might possess; and an otherwise intelligent mother informed me once that she declined to go on with a treatment in which a surgeon's personal attention was necessary at intervals of two or three months, when her instrument-maker could supply her with a steel and leather support that would last for years! And this may be taken as a fair sample of what many said or implied.

When I add that leading instrument-makers advertised in the past that they put on 'Sayre's jackets' for the profession, and also that leading surgeons sent their cases to them for the purpose, and when I know of my own knowledge that the jackets were nothing but stiff plaster belly-bands, rapidly excoriating the flanks, and worse than useless, and their uselessness made known as demonstrative of the futility of 'Sayrism'—it is not surprising to find that the plaster jacket had to give way to steel, leather, and felt, which materials now reign supreme.

However, the lesson taught by Sayrism has not been lost entirely; felt jackets, though an imperfect support, more nearly fulfill the principles of that system than the old steel and leather supports; and even those who still use the latter endeavor to get them more body-fitting than formerly.

"Re Spondylitis: (b) The Tripod Exercise.—I only use the tripod for the application of the jacket. In a stage when exercise might indeed somewhat unfold the spine by extension upon recently formed reparative material, I should consider its use as an exercise unwise; while where consolidation has occurred, it would be useless.

The exception I make is in the case of deformity, after consolidation, being such in the dorsal region as to cause the chest to assume the position of deep expiration; then exercise, by acting through the thoraco-lumbar muscles, undoubtedly, as in
MacNaughton-Jones, London: "In reply to your letter I send you the photograph of the first patient on whom a plaster-of-Paris jacket was put in Ireland in the year 1876. It was adjusted by me prior to your visit to Cork that same year. Since that date to the present I have practised the treatment there advocated by you, so far as suspension and support are concerned. Necessarily of late years my work has not carried me so much into this field of surgery as it did in Ireland. As you know, I published the results of my cases up to a certain date in the Dublin Monthly Journal of Medical Science. You want to know what is my present view of the results of your plan of treatment in spondylitis and scoliosis.

First, Spondylitis. I regard the jacket well adjusted in the early stages of the disease as the most valuable support to the diseased structures I know of (I include in this statement all the hybrid deviations which imitators of your method have adopted), so long as the integrity of the support is secured and maintained. This, so far as I can judge, is essential. The head support I also include in this view. The treatment in the early stages should be, I hold, combined with a fair amount of rest in the horizontal position and all the other hygiene and locomotive aids which are so essential in this treatment.

Given a fair case and prudent supervision with judicious change of the support, it is the treatment which I should adopt in the case of a child of mine affected with the disease. Certain cases of spondylitis, in which general tubercular affections of the various bones are present, can be cured by no treatment I know of. Deformity is inevitable, do what we will. I do not suspend in Pott's disease save in placing the jacket on the patient. This latter is no hindrance to treating the complications of the disease. This I have proved many times. In the latter stages, when the support has done its work, I resort to the well-fitting plaster-of-Paris jacket with steel stays and the softened portion for the affected area. This I can combine with light arm supports and the head rest if necessary. This is my view of the plan you advocated, and which has stood (though so often twisted and turned for some faddist's personal advertisement as hardly to be recognized as yours) the test of the last twenty years. If the principle has failed, it has been from trial when no cure was possible, in cases in which nothing was to be expected from any plan of treatment, or it has been carried out ineffectually and imperfectly.

Scoliosis. I can not speak too warmly of my experience of the suspension treatment in scoliosis. I may have departed in a degree from my original practice in always employing the plaster jacket, pernicious unwise in some instances. I now, I fancy, in the cases that I am consulted in, use plaster. I use the non-plastic felt, carefully molded and applied under suspension, in all cases. I support the jacket with stays of steel where required, and combine at times light axilla props. I invariably insist on the practice of suspension by the neck at home, and combine the treatment with gymnastic exercises and the usual rules of hygiene and diet followed in such cases, I can unhesitatingly say that such treatment gives but the best results. I have never, since I put on the jacket I send you the photograph of, resorted to any other mode of treatment in any form of lateral curvature. I believe it to be the best. As a general rule, it has given me such good results that I have never been tempted to go outside it. Even in old and irreparable cases it has given the greatest comfort and relief from pain.

In conclusion, let me, as one who has on many an occasion reaped the benefit of your inventive skill and sound practical teaching in this branch of orthopaedic surgery, as in many others, pay no mere flattering tribute to the system of treatment you so graphically introduced into this country. But the real testimony to its worth is one you may neither see nor hear. It is the unrecorded and unspoken gratitude of the many whose lives have been spared, whose sufferings have been mitigated, and deformities removed through your own work, and of those who have followed in your footsteps. This is true of the past, it is equally so of the present, and it is my belief it will be so in the future."

E. Luke Freer, Birmingham: "My experience with plaster-of-Paris jackets dates from Dr. Sayre's demonstration in Birmingham some fifteen years ago, one of the patients being supplied by me from the Birmingham Royal Orthopaedic Hospital, where I then held the post of honorary assistant surgeon. In that capacity I applied every plaster jacket for my senior colleagues (in those days everything 'spinal' was turtle-shelled indiscriminately), and I might almost have been dubbed 'honor-ary plasterer' to the hospital. As might have been expected, the results were not universally satisfactory. As honorary surgeon, I have dealt only with my own cases, but my applications have numbered over three thousand altogether, and I am now as firmly convinced as ever of the superiority of the plaster cuirass over all other methods for the treatment of spondylitis; where recumbency was necessary in cases of abscess, etc., I have found Thomas's double hip splint very serviceable. In high dorsal and cervical cases I have preferred Farnneau Jordan's modification, and in some cases Thomas's collar, to the jury-mast, as giving more complete fixation. In scoliosis (unassociated with spondylitis) I still use the cuirass, but only when the patient has to pursue his or her ordinary vocations, or at the commencement of treatment, until the muscles and muscular sense have been sufficiently re-educated and strengthened by systematic and harmonious kinetics and the correction of faulty positions, never when reclining or performing the exercises. I consider the constant use of the cuirass prejudicial in these cases, and I always use the divided cuirass with elastic lacing in scoliosis. I am convinced that the opposition to the cuirass has been mainly due to improper application, and the omission of the long 'reflected' vest which meets all objections on the score of 'chirping.' Elaborate instruments with ratchets and pads I consider are worse than useless—the tortures of the Spanish Inquisition would seem to be the models on which some of them were fashioned.

If I may be allowed to speak freely, I think that much of the present antagonism to the cuirass is due to the fact that
Professor Sayre, in his excellent and explicit monograph, was rather too sanguine in stating that any practitioner could apply it. Many of the so-called plaster jackets I have seen were simply burlesques of the principles involved, and in this country the application has most frequently been relegated to nurses. I know of no operation, however, that depends more on strict attention to minor details for success, which details are only to be learned by experience. Poroplastic I have entirely discarded, as it is impossible to get it perfectly and accurately molded to the body, even where the deviation from the normal is slight. Again, it has nothing to recommend it even on the scores of expense or weight. Several of my cases have worn the divided plaster cuirass for more than twelve months with perfect comfort, the weight being no more than poroplastic. I continue to use partial suspension also in addition to other kinetics, especially in high dorsal curves and torticollis, with the best results."

W. Bayard, St. John, N. B.: "It affords me much pleasure to say to you, and I do so in all sincerity, that I consider your 'plaster jacket' a boon to the profession and to the unfortunate sufferer with spondylitis. I have used it largely for many years—indeed, I use none other—and I can point with pride to individuals walking our streets who, but for Sayre's jacket, would in all probability be in their graves. I have added various materials to the plaster with the view of rendering it less brittle, but I have found its porosity injured, so that I now use nothing but the plaster.

"In some instances I have inserted strips of steel, such as are used in ladies' corsets, between the bandages with benefit. When applying the bandage I always allow the patient's feet to touch the floor, and if he complains of pain in his legs I cease suspending, and I open the jacket for ablation purposes.

"I prefer the plaster jacket for scoliosis to any mechanical application I have seen, but I never trust to it alone, recommending such muscular exercises as the particular case demands.

"I may mention a traumatic case where the jacket answered admirably. A man was sitting under a heavy wheel when the supports broke; the wheel caught him on the shoulders, doubling him forward. I saw him immediately after the accident; he had no power in his legs, but yelled with the pain in them. I had him place face down, with a man at each shoulder and at each foot, directed to make steady extension, while I made gentle pressure upon the prominence produced by the altered position of the vertebræ. In a moment or two the power of motion returned and the pain ceased. He was taken home on a door; the next day I placed your jacket on him, and kept him in bed ten weeks. He wore a jacket for two years, after which he was as strong as ever."

J. Nicolaysen, Christiania, Norway: "I have used your treatment of spondylitis and scoliosis by partial suspension and retention by plaster-of-Paris bandages since the time you first brought it forward for the public.

"I have always been very content with the results of this treatment; the results have naturally been more or less perfect after the condition of the patients, especially after the stadium of the diseases, when the treatment could be instituted; but always the condition has been bettered, in most cases for the life; I know not of any better treatment."

Enrique M. Porto, Havana: "... In conclusion: In angular curvatures of the spine the Paris-plaster bandage is the only and exclusively local treatment, and in slight lateral curvature partial suspension and exercise combined is a good treatment, but I find it better if aided by retention of body by plaster-of-Paris bandage."

Since 1877 I have treated most of my cases of spondylitis by means of the plaster-of-Paris jacket, using very slight extension, always taking care not to break up or injure any bone adhesion of the spinal column.

The great majority of patients treated in this manner did well. When this treatment failed, rest on a couch, together with some form of extension, was adopted, and after a time the plaster-of-Paris jacket was reapplied.

With regard to scoliosis, I have had the great privilege of seeing many cases treated by Professor Sayre himself. I have adopted and highly approve of his method of treatment by extension, using the exercises recommended by Dr. Reginald Sayre, and the cuirass as a support during the day in severe cases. But I have substituted the felt poroplastic jacket for the plaster cuirass, because I found that, owing to the extreme dampness of our climate, I was not as successful with my plaster-of-Paris work as Dr. Sayre had been with his.

Nicholas Gattan.

H. Hingston, Montreal, Canada: "In those cases of curvature arising from disease when uniform and comfort-giving support is of advantage, no surgical appliance, however well fashioned it may have been, gives me anything like the satisfaction I have had in the use of the simple and inexpensive support Dr. Lewis A. Sayre has given to the profession."

Pittsburgh, Pa., December 31, 1894.

Dr. Lewis A. Sayre, New York:

Dear Doctor: I find that I will be unable to have the paper, now in preparation, upon Spondylitis and Scoliosis, completed in time to send you an advance copy, as per promise. It will not likely, however, contain anything that would be of particular value to you in the preparation of your paper. My treatment for the cases is based upon the plan as carried out by yourself and others. I use suspension, gymnastics, forcible correction, and retention by plaster-of-Paris bandages.

Shall look forward with a great deal of interest for the appearance of your paper, which I know will be of great value to us. Yours truly,

S. L. McCurdy.

Dr. Redard, Paris: "In answer to the questions which you have been kind enough to ask me, I would say, I am a convinced partisan, first, of suspension and plaster jackets in the treatment of scoliosis; second, of plaster jackets in the treatment of Pott's disease at a certain stage.

"In the treatment of scoliosis I recommend vertical suspension in cases of slight rigidity of the spinal column, and daily exercises as a preparation for the application of plaster jackets.

"Vertical suspension is the basis of a great number of exercises carried out with the different apparatus which are described in my work on Orthopaedic Surgery.

"In a great number of cases where there is pronounced rigidity of the spinal column, I use my apparatus for lateral suspension. The removable corset gives excellent results in a great number of cases of scoliosis which, in my opinion, however, are not obtained solely by its use, but in conjunction with proper exercises to strengthen the vertical muscles and restore the flexibility and proper position of the spinal column.

"It is of particular value where the spine is movable and not rigid, and where suspension corrects the deformity to a great extent; in these cases the faulty attitude is partially overcome, the lateral curve is very much modified, and the height of the patient is increased. In the interval between the exercises the patient is well supported, the pressure on the various points of the thorax forces him to take a correct position, and
he does not lose the benefit gained by the various exercises used to correct the deformity.

"To sum up, the plaster corset is of particular value as a means of support after the rigid spinal column has been rendered flexible by the methodical use of exercises properly carried out.

"Experience has taught me that exercises very little influence on the deformity of the ribs, or the twisting of the spinal column.

"I would further say I do not use plaster corsets in the early stages of scoliosis. I recommend it in cases where there is a lateral flexion and where the vertical curve has been partially overcome by the use of vertical suspension. I have obtained excellent results in some cases of scoliosis in its second stage, by combining the treatment of plaster jackets and exercises with mechanical force in straightening the spinal column. The plaster jacket has been particularly valuable in my hospital practice, in very marked cases of scoliosis accompanied by pain and disturbances both of circulation and respiration. In these cases it has been of great benefit by supporting the body, preventing injurious compression of the organs of the thorax and abdomen, and greatly diminishing the pain.

"In the treatment of Pott's disease, when the disease is in the cervical region or accompanied by paraplegia, I employ suspension, placing the patient in an oblique or vertical position on a padded board.

"In the first stage of Pott's disease I prefer absolute rest in the horizontal position. I have obtained excellent results from the application of the plaster jacket at the period of reparation and consolidation of the spinal column, when it has been possible to prevent deformity and often pain has entirely disappeared, the result of entire rest in the horizontal position.

"According to my experience in some exceptional cases, the plaster jacket prevents, to some extent, the deformity in Pott's disease.

"I do not agree with some authors that this jacket can give extension to the two segments of the spinal column, and reduce pronounced curvature. The principal function of the apparatus is to obtain absolute rest and immobility for the diseased parts, and thus arrest the progress of the disease.

"In cases of Pott's disease in the cervical region the plaster jacket is of little use."

From this number of letters which, I take it, expresses pretty fairly the general opinion of the medical profession, I find six who condemn the plan altogether, or, at any rate, say that they do not use it; seven who say that in certain cases it is of use, and in others less serviceable in their hands than different means, and thirty-five who employ this mode of treatment altogether. Among the objections to their use, which have been set forth in the letters I have received, are those of Noble Smith, who says that "plaster of Paris jackets ought to be utterly condemned—first, because of their great weight; second, their interference with free respiration and cleanliness; and, third, the fact that they act simply as heavy, unscientific corsets, pressing upon the chest, and add very little to support the spine."

I may simply answer these objections by saying that a properly made plaster jacket is but slightly heavier than a steel support, and in many instances is even lighter; that, when properly applied, embarrassment of respiration is caused by the pain which free respiratory movements give the spine in Pott's disease, and not on account of constriction of the plaster jacket; and that, as far as cleanliness goes, the patients who are clean before the application of the jacket, and are properly attended to by careful parents or nurses, remain clean, and that the accumulated evidence of many prominent physicians is a better refutation than anything I personally can say of the charge that they are "heavy, unscientific corsets, pressing upon the chest, and adding very little to support the spine."

Of the various substitutes that have been used instead of plaster of Paris, silicate of sodium can be as accurately fitted; but it is so much longer in setting that it is extremely difficult to make a good-fitting jacket on the patient, unless a plaster shell is placed outside of it to retain it in position until the silicate of sodium has become hard. Or else the silicate jacket is made over a model, which adds greatly to the trouble of making the jacket. It also has the disadvantage of not allowing the insensible perspiration to pass through it, as does the plaster of Paris. This is apparent from the illustration of these two models, which represent two plaster jackets, covered in, top and bottom, with a small hole in one end to allow of the insertion of the stem of a tobacco pipe. One has been varnished and the other has not. Through the unvarnished one you see the smoke passes freely when I blow it inside the jacket; the other is impervious. In regard to felt, paper, wood, aluminum, leather, and celluloid, I would say that the felt, to my mind, is decidedly inferior to the plaster of Paris, being very little lighter, and in hot weather much more offensive. The objection to leather is that it is more liable to warp, and also the fact that it becomes offensive in hot weather. The celluloid, wood, paper, and aluminum jackets are lighter than the plaster of Paris, but have this disadvantage, that they require the services of a skilled artisan to construct them, and that they are beyond the reach of people of small means, who live at a distance from large towns, and a practical experience with them, as worn by different patients and manufactured by different surgeons, has shown me, that they are much more difficult to adjust, so as to give comfort to the patient equal to that afforded by the plaster jacket. The principle, however, is that for which I strive—namely, the adapting of some plastic material to the body in cases of Pott's disease, in a position of comfort, and in lateral curvature in the position of best possible form, for the purpose of retaining the body continually in these improved positions—and the material of which the jacket is constructed is not essential, so long as the principle is carried out, though I think, in the vast majority of cases, that plaster of Paris will be found greatly superior to the other materials that I have mentioned on account of its cheapness and ease of application.

APPENDIX.

BERLIN, December 23, 1894.

DEAR DE. SAYRE: Owing to an unaccountable error I was under the impression that you would not deliver your address before January 15th, and therefore I had hoped to employ some leisure time at Christmas in fulfilling your request. To my great dismay, I see that the date is January 3d, not 15th, and that it is scarcely possible now for my answer to reach you in time.

I should feel inconsolable for this mistake were it not for
the conviction that I can give you no information of importance, so that for you it is a matter of comparative indifference whether you receive my answer before or after your address.

From your great good nature I will trust that you will pardon me and not judge me too harshly.

With this letter I venture to send you a short article published in 1889, not because I think that it possesses any value, because your adjustable jackets are much simpler and more practical, but I wish to show you that I have always felt a keen interest in your method of treatment, which I consider a great advance on previous methods.

That I have, however, used portable plaster jackets only in a few cases during the last ten to twelve years is owing principally to reasons which in themselves have but slight connection with your method.

These reasons I will endeavor to give you briefly.

There is no necessity for me to enlarge at present upon the advantages of your beautiful plaster jackets, which are as familiar to yourself as to me. They are readily applied, are light, porous, cheap, obtainable anywhere, and—a fact upon which I lay as much stress as you do—they enable the physician to treat the case personally from beginning to end.

My reasons for adopting other styles of jackets in spite of all this are as follows:

In spite of all my efforts I could not succeed in giving the plaster jackets that durability which many of my patients required. A large proportion of my patients I see but once a year, some of them but once in two or three years, or not even so often as this, as they do not live in Berlin, and not a few—especially the older ones—require that their jackets should last several years.

The plaster jackets, like all which are of unyielding material, do not allow of sufficient discrimination; in slight or severe scoliosis the same jacket is always employed. As I treat even the mild cases with jackets, as well as gymnastics and massage, and consider the use of the jacket as the most important part of the treatment, it becomes necessary for me to have jackets of varied construction to suit special cases. In slight scoliosis I use simpler forms, which are, of course, less constraining. In severe scoliosis and spondylitis I use more complicated forms.

Elderly people, especially women, feel very uncomfortable in the stiff jackets; they complain of pressure, impeded breathing, etc., inconveniences which can be avoided by the use of steel-drill* jackets without losing the advantages of a sufficient support to the body.

Very young women often assert that the plaster jackets, and those of felt and wool, disfigure them more than the scoliosis itself, greatly increasing the size of the waist; further, they find them especially unpleasant in dancing. These disadvantages are not so manifest in the steel-drill jackets.

From my own observation I am of the opinion that the muscular tissue wastes away more quickly under the rigid material than under the steel-drill jackets.

Therefore I now use the plaster jackets only among the poorer classes, or in cases of spondylitis where a good support is required, until a suitable felt jacket can be provided.

In cases of severe scoliosis of little children, as also in spondylitis—in acute stages of the latter as a temporary means—I use felt-steel jackets made on a plaster model and working in exactly the same way as your plaster jackets. So soon as the pelvis is sufficiently developed to give a proper support, I prefer to use in spondylitis the steel-drill jackets with hip attachments and firm arm supports.

Partial suspension I make use of in preparing the models for felt-steel corsets and also as a gymnastic exercise in the treatment of scoliosis. For the latter purpose it is widely used in Germany.

Begging once more that you will kindly pardon my neglect, and that you will remember me most cordially to Dr. Reginald Sayre, I remain with much esteem and best wishes for the new year,

Yours most truly,

Flor. Beely.

Odessa, December 23, 1889.

Dear Sir: In answer to your kind letter I communicate you what follows:

In the treatment of spondylitis and scoliosis I consider portable apparatus as a very important factor.

In the beginning of my six-years-long practice I used to employ with success in the polyclinical cases the immovable plaster-of-Paris corsets; in private practice, when the patient's means allowed it, I applied wooden stays. Lately, in the first above-mentioned case I continue to use the same corsets, while in the last I apply Hessing's stiff-stays.

I use the plaster-of-Paris stays in the following way:

Partial suspension after "Beely," with that difference, that at Beely's the patients touch earth only with the tippets, while I find it sufficient when they touch it swiftly with the whole sole. On the body of the patient, done over with vaseline or covered with thin jersey, I apply a slight layer of ordinary richly gypsumed bandages of starched stiff gauze (not above two millimetres). When, after one to two minutes, that layer is congealed, I do it over again on of stays, bandages (thick-starched stiff gauze, little gypsum). When the layer has attained the thickness of three to four millimetres and is hard, I take off the whole by making a slit in front and immediately take out from inside the first thin layer, which parts very easily, as it is separated from the plaster-of-Paris corset itself by a layer of vaseline.

The advantages of the method are:

1. The absence of folets on the inner part of the stays.
2. On the hardened surface the stays become firmer, thinner, neater.

After having been dried in the drying room, or in summer in the sun, such stays fit exactly the body, as they contract while dried.

The dry stays are covered inside and outside with jersey by means of starch gum, their edges finished with dogskin; the stay lace is sewed on, etc.

The technique of wooden stays is explained in the herewith joined article. The technique of Hessing's stays is described, as you know, in the Lehrbuch der orthopäd. Chir., von Albert Hoffa.

In the present time I use the plaster-of-Paris stays only when Hessing's stays are inaccessible for the patient on account of their price. The fixation of Hessing's stays is the most perfect, as well in cases of spondylitis as in those of scoliosis. The wearing of stiff stays, bound with steel, is much more agreeable to the patient than that of any hard stays, even the most perfect.

Patients that have worn hard stays, even of the lightest kind—as those of felt, of wood, or of celluloid—when they get Hessing's stays, that weigh much more, assert them to be much lighter, because they lie softly on the body. I consider as the principal defect of all hard stays, not excepting the plaster-of-Paris corsets, that they do not fit firmly in the waist. That defect impedes, especially in the treatment of spondylitis of the higher pectoral vertebrae, when the jury-mast is added to the stays, for the fixation of any hard stays on the pelvis is precarious.

As the use of hard stays is inevitable, Hessing's stays being

* That is, cloth supported by steel bands.
The Significance of the Presence of Lactic Acid in the Stomach.

By JULIUS FRIEDENWALD, A. B., M.D.,
CLINICAL PROFESSOR OF DISEASES OF THE STOMACH,
COLLEGE OF PHYSICIANS AND SURGEONS;
VISITING PHYSICIAN TO RAY VIEW HOSPITAL, BALTIMORE.

(From the Department of Clinical Medicine, College of Physicians and Surgeons, Baltimore.)

The presence of lactic acid in the stomach is of great interest to the physiologist as well as to the physician. Since the publication of the classic experiments of Ewald and Boas, it has been generally believed that lactic acid is a normal constituent of the gastric contents. These writers showed that after the introduction of an ordinary test breakfast of water and a roll, lactic acid was the first to make its appearance; there was then a period during which both lactic and hydrochloric acids were present, the former being much decreased in quantity; at the end of an hour, hydrochloric acid alone could be detected.

It is held by many recent writers that lactic acid is a normal constituent of the gastric contents, and that in certain pathological conditions it is likewise frequently found during the entire period of gastric digestion. The conditions referred to are those in which hydrochloric acid is absent, as in chronic gastritis, especially when there is marked motor disturbance of the stomach. The production of lactic acid was ascribed to the fermentation of the carbohydrates of the test meal, and its disappearance was attributed to the presence of sufficient free hydrochloric acid. These results were obtained by means of Uffelmann’s test; this, as is well known, is performed as follows:

One or two drops of a neutral ferric-chloride solution are added to ten cubic centimetres of a one-per-cent. solution of carabolic acid, and the mixture is diluted with water until it assumes an amethyst-blue color. To a few cubic centimetres of this solution a small quantity of gastric juice is added; if lactic acid is present the liquid assumes a yellow color. Those who have frequently used this reagent for detecting lactic acid know how variable the yellow is: sometimes there is the merest shade of yellow; at others, an intensely yellow color is produced. We frequently find such expressions as “slight,” “doubtful,” “intense” reaction in literature. A number of years ago, Boas called attention to this fact, and laid stress upon the point that such designations were absurd, and that only an intense canary-colored yellow “Zeisierfärbung” could be relied on. In a later communication, On the Significance of Lactic Acid in Cancer of the Stomach, he draws attention to the fact that the canary-yellow color is indicative of cancer of the stomach.

It is now known that Uffelmann’s test is not reliable, for by its means similar reactions may be obtained with other organic acids, glucose, and alcohol (which are frequently present in the gastric contents), and furthermore for the reason that hydrochloric acid and the phosphates may prevent the reaction when lactic acid is in fact present.

Martins and Lüttke were the first to show that lactic acid was not a normal constituent of the gastric contents. They determined: \( \text{A} \), total acidity (with phenolphthalein); \( a \), total chlorine; \( b \), chlorine in chlorides. \( (a - b) = \) hydrochloric acid secreted; \( \text{A} - (a - b) = \) lactic acid.

They examined the gastric contents of healthy individuals after an Ewald-Boas test breakfast. The stomach was expressed of its contents five minutes after the breakfast had been administered, and at five-minute intervals thereafter. By this indirect method they determined that the total acidity and amount of hydrochloric acid produced were exactly the same. This was, therefore, the proof that lactic acid was not produced. The presence, therefore, of lactic acid in any considerable amount signifies a pathological condition.

[Additional references follow, but are not included here for brevity.]
In a review of Martins and Lüttke's monograph, Boas* points out that the absence of lactic acid in normal conditions was proved in an indirect manner only by these investigators, and that further and more convincing evidence was needed. Much credit is due Boas for the solution of this problem. Inasmuch as Uffelmann's reagent was not sufficiently delicate, a new method † for the determination of lactic acid had to be devised. This method is based on the principle that a solution of lactic acid, when carefully heated with strongly oxidizing substances, is decomposed into acetic aldehyde and formic acid. The aldehyde is detected by the formation of iodoform in an alkaline solution of iodoform. The qualitative determination is made as follows:

Ten cubic centimetres of gastric filtrate are evaporated to a syrup in a porcelain dish over a water bath. If free acids are present (which may be determined with Congo paper), an excess of barium carbonate is added before evaporation. A few drops of phosphoric acid are now added to the syrup and the carbon dioxide removed by boiling for a moment. The mass is now allowed to cool, and treated two or three times with fifty cubic centimetres of ether ‡ to remove the carbohydrates, for these likewise form aldehyde when oxidized. After digesting for half an hour, the clear ether layer is poured off, the ether evaporated, and the residue washed into a flask with forty-five cubic centimetres of water; the flask is shaken up and, if necessary, the mixture is filtered. The filtrate is treated with five cubic centimetres of concentrated sulphuric acid (specific gravity, 1-84) and a small quantity of manganese dioxide. A perforated cork, into which a bent piece of tubing is placed, is fitted into the flask; the tubing is led into a small cylinder containing an alkaline iodoform solution (equal parts of a one-tenth normal iodoform solution and normal sodium hydride). The flask is now carefully heated over a small Bunsen flame, and as soon as the boiling begins the iodoform solution becomes cloudy and the odor of iodoform is detected.

The quantitative method for the determination of lactic acid is similar to the qualitative method. After the evaporation of the ether, the residue is washed into a flask with forty-five cubic centimetres of water, and five cubic centimetres of sulphuric acid and manganese dioxide are added. The contents of the flask are now carefully distilled until four fifths of the fluid have passed over. The distillate is collected in a flask containing twenty cubic centimetres of water (a piece of glass tubing being connected with the still and reaching into the water).

The solutions required for the estimation of the lactic acid are the following:

1. One-tenth normal iodoform solution.
2. One-tenth normal sodium arsenite solution.
3. HCl of a specific gravity 1.018.
4. KOH (fifty-six grammes KOH to a liter of water).

‡ The ether must be absolutely free from alcohol.

5. A freshly prepared thin solution of starch paste.

The alkaline iodoform solution is added to the distillate (usually ten cubic centimetres of one-tenth normal iodoform solution dissolved in ten cubic centimetres of the KOH solution). The flask is now closed and the mixture allowed to stand for a few minutes. Twenty cubic centimetres of normal HCl are next added, and then sodium bicarbonate in excess and one-tenth normal sodium arsenite until the mixture is entirely decolorized. The excess of sodium arsenite is now titrated back with a one-tenth normal iodoform solution (the starch solution having previously been added) until a blue color appears which does not disappear on stirring. The number of cubic centimetres of one-tenth normal iodoform minus the number of cubic centimetres of a one-tenth normal sodium arsenite used, indicates the amount of iodoform necessary to form iodoform and indirectly the amount of lactic acid.

The calculation of lactic acid depends on the principle discovered by Boas,* that one cubic centimetre of one-tenth-normal iodoform solution corresponds exactly to 0-03388 grammes lactic acid; so that it is only necessary to multiply the number of cubic centimetres of one-tenth normal iodoform by 0-03388 to determine the amount of lactic acid.

Example: Amount of one-tenth normal iodoform at first used, 10 cubic centimetres. Titration with one-tenth normal sodium arsenite, 7 cubic centimetres. One-tenth normal iodoform needed to titrate back, 0-5 cubic centimetre. Therefore the whole amount of iodoform used is 10-5 cubic centimetres. Minus the whole amount of sodium arsenite, 7 cubic centimetres. Leaving, therefore, to form iodoform, 2·5 cubic centimetres. The amount of lactic acid is consequently 2·5 × 0-03388 = 0-0847 for 10 cubic centimetres, or 0-0847 per cent.

By this method Boas found that the roll of bread of the ordinary Ewali-Boas test breakfast contains considerable quantities of lactic acid; this was also found true of all forms of baked carbohydrate food, such as crackers, zwieback, so that all results in regard to the production of lactic acid in the stomach based upon such test meals are wholly fallacious. A test meal entirely devoid of lactic acid was sought. This was found in the form of a simple flour soup consisting of a tablespoonful of flour to the liter of water.† The ether extract of such a soup does not produce on oxidation the slightest traces of aldehyde, and therefore does not contain any lactic acid.

Employing such a test meal and using his new method, Boas ‡ determined the "presence of lactic acid in health and disease." He found that under normal conditions lactic acid is not produced during any stage of digestion. It was not found in five cases of chronic gastritis, five cases of atony, and six cases of dilatation (non-malignant forms). From these results he concluded that, notwithstanding an
absence of free hydrochloric acid and the presence of marked motor insufficiency (conditions usually considered most favorable for the production of lactic acid), this acid need not be produced after the introduction of carbohydrate food; a third factor is necessary for its production.

In thirteen out of fourteen cases of cancer of the stomach lactic acid was found in rather large quantities (from 0.13 to 0.382 per cent.), though the stomach had been previously washed out and the test meal had remained in overnight. In four cases it was found very early in the course of the disease, long before the tumor could be palpated. The conclusion is therefore reached that lactic acid as found by this new method is an early diagnostic sign of cancer of the stomach. Boas, however, draws attention to the fact that the absence of lactic acid is not necessarily indicative of the absence of cancer.

In a recent communication from Boas's polyclinic, Oppler* brings forward the following new observations concerning the production of lactic acid in cancer of the stomach:

1. Lactic acid is found in the gastric contents in large quantities in those cases of cancer in which marked motor disturbance is associated with an absence of free hydrochloric acid. In these cases sarcinae are always present.

2. Lactic acid may be found in those cases of cancer in which the motor functions are normal and free hydrochloric acid is absent. In these cases sarcinae are absent.

3. Lactic acid is never found when the motor function is disturbed and free hydrochloric acid is present. Sarcinae are found in these cases.

Oppler has discovered peculiar slender bacilli grouped in chains in those cases of gastric cancer in which lactic acid is formed. Inasmuch as he was unable to cultivate these organisms on any of our known media, he can not state what relation they bear to the production of lactic acid in the stomach.

The work of certain authors tends to verify the correctness of Boas's views in regard to the production of lactic acid in cancer of the stomach. Thus Schüle,† Strauss,‡ Hammerschlag,§ and Mintz∥ arrive at the same conclusion. But few observers have found large quantities of lactic acid as determined by a real Uffelmann's reaction (canyary-yellow color) after an ordinary test breakfast of bread and water in conditions other than cancer; none have found it after the flour-soup meal, when examined according to the method of Boas, except in that disease.

Special attention has been recently directed to those rare cases in which lactic acid was found in non-cancerous conditions. There are a few cases reported by Strauss, one case of Thayer,* and one of Rosenheim.† These examinations were made without previous lavage and after an ordinary Ewald-Boas test breakfast, Uffelmann's reagent being employed.

It is probable that the lactic acid was introduced with the test breakfast. The cases of Thayer and Rosenheim are especially interesting.

In both there was a marked dilatation of the stomach, a palpable tumor, absence of free hydrochloric acid, and presence of lactic acid, as determined by Uffelmann's reagent. There was marked emaciation in both cases. Thayer's patient was twenty-two years old, Rosenheim's fifty-eight years. The autopsies revealed a stricture of the pylorus, with ulceration, in Thayer's case; an hypertrophy of the pylorus, with an atrophy of the gastric mucous membrane, in Rosenheim's case; in neither was there a cancer.

Inasmuch as the examinations were made before the introduction of the new form of test meal and before all the necessary precautions were known, they lose their importance.

In our own experiments the contents of the normal and the diseased stomach were examined with a view to determine the absence or presence of lactic acid.

The first table represents the normal cases. Of these, there were three cases of perfectly normal digestion, and six cases of nervous dyspepsia, in which the motor and secretory functions were perfectly normal. The examinations numbered twenty-nine in all. In every case the

* Thayer. Bul. of the Johns Hopkins Hospital, 1893, No. 31.
stomach was thoroughly washed before a flour test meal of Boas, consisting of a litre of flour soup (one tablespoonful of flour to the litre of water), was given. The stomach was expressed of its contents at various intervals, as represented in the table (five to sixty minutes), so that every period of digestion was studied. In some cases a part of the contents was removed, and after an interval the remainder. Never were more than two expressions made on the same day.

The contents were examined for lactic acid according to Boas's method, for free HCl with phloroglucin-vanillin, for HCl and organic acids according to Heyner-Seeman. This last method served as a control in the estimation of organic acids.

From these experiments it is conclusively shown that, under normal conditions, lactic acid is never produced during any period of digestion after the introduction of carbohydrate food into the stomach.

The occurrence of lactic acid in various diseases of the stomach was next studied. These included four cases of superacidity, eight cases of atony, two cases of dilatation (non-malignant), eight cases of chronic gastritis, four cases of secondary gastric catarrh, and four cases of cancer of the stomach.

Table II. Cases of Superacidity.—Of the four cases of superacidity, one was a marked case of supersecretion, one a doubtful case of ulcer, and the two remaining cases nervous dyspepsias. In all there were high percentages of free hydrochloric acid of over 0.3 per cent. The stomach was expressed of its contents an hour after the flour-soup test meal. In none was lactic acid found.

In Table IV are represented the cases of dilatation. Case I suffered with a marked motor insufficiency, the dilatation being due to the narrowing of the pylorus, probably from cicatrized ulcer. Case II is especially interesting.

The patient, F. H., fifty years of age, had complained of dyspeptic symptoms for several months before consulting me. Previously he had always been in good health and able to eat and digest all forms of food. The gastric disturbance came on rather suddenly with a violent attack of vomiting and purging. After a few days the patient felt better, but soon after there was constant nausea, occasional vomiting of large quantities of undigested food, pain in the epigastrium, frequently constipation followed by severe attacks of diarrhoea. There was an entire loss of appetite and headaches were frequent.

On examination, the patient was found rather badly nourished, mucous membranes pale, pulse rather weak, tongue coated; heart, lungs, and urine normal. The abdomen was rather tender to pressure; no resistance could be felt anywhere. By quick shocks with the hand upon the abdomen a splashing sound could be elicited as low as three fingers' breadth below the umbilicus, which was found by subsequent inflation of the stomach with air to be the position of the greater curvature. Even with very small quantities of fluid in the stomach (one hundred cubic centimetres), a marked succussion sound was produced. Frequent expressions of the gastric contents after an Ewald-Boas test breakfast always brought forth large quantities of badly digested contents of an acidity ranging from eight to ten, without any free hydrochloric acid. The expression of the contents of the stomach before the ingestion of any food in the morning after a Boas test supper had been given the evening before brought forth food remains. The examination of the gastric contents with Uffolmann's reagent always gave a doubtful lactic-acid reaction. Repeated examinations were made for lactic acid, according to Boas's method, with the flour-soup test meal. Expressions were made in from three to seven hours. Lactic acid was never found. For several months the patient
grew worse, suffered much from constipation and became markedly emaciated, notwithstanding the usual dietetic treatment, the use of lavage, intragastric faradization and galvanization, use of hydrochloric acid, etc. On account of the continued absence of lactic acid from the gastric contents and the absence of a palpable tumor, the diagnosis of chronic gastritis with dilatation was made. The subsequent history of the case showed this diagnosis to be correct; for after a few months the patient began to feel better, gained flesh, and now, after a year over his first visit, his general health is good and he suffers but little, though there is still a marked motor insufficiency with entire absence of free hydrochloric acid.

This case shows that lactic acid need not be produced even if there is marked motor insufficiency with entire absence of free hydrochloric acid.

In Table V are represented the cases of chronic gastritis. The examinations were made half an hour to an hour after the ingestion of the flour-soup test meal. In but one case (Case V) mere traces of lactic acid were found (these probably having been swallowed).

It is thus shown that a mere absence of free hydrochloric acid is not in itself sufficient to cause the production of lactic acid in the stomach.

Table VI contains the cases of secondary gastric catarrh. Of these, three were due to pulmonary tuberculosis and one to heart disease. In all there was an absence of free hydrochloric acid and an absence of lactic acid.

Our investigations have therefore shown that lactic acid is never produced after the ingestion of carbohydrate food in any chronic non-malignant disease of the stomach.

Four cases of cancer were examined according to the method of Boas (Table VII). The flour test-meal was allowed to remain in the stomach overnight, and was removed in nine or ten hours after its introduction, a marked motor insufficiency (dilatation) being present in all the cases. In all there was an absence of free hydrochloric acid; in all large quantities of lactic acid were found with both Uffelmann's and Boas's methods.

</table>

Three were cases of pyloric cancer with dilatation; one of cardiaic and pyloric cancer, with dilatation and nodules in the liver. Three of these cases have since died.

These cases show that in cancer of the stomach large quantities of lactic acid may be produced in the stomach.

It must be remembered, however, that there are cases of cancer in which lactic acid does not appear. The presence of lactic acid indicates cancer; its absence does not prove the opposite. Other cases of cancer were examined with reference to the formation of lactic acid, but only with Uffelmann's reagent. I therefore omit them from this list.

From our numerous observations we are enabled to confirm Boas's statements, and conclude that lactic acid is not formed during digestion in the normal or in the diseased stomach, excepting cancer, but that in this disease it is usually produced in great quantities. Furthermore, that Uffelmann's test is to be relied upon only in those cases in which the reaction is very marked and decided, and never unless the stomach has been previously carefully washed and a simple flour test meal ingested. We can heartily recommend Boas's method for accuracy and reliability.

[Note.—Since the foregoing was written an article by Dr. D. D. Stewart, on A New Diagnostic Sign for the Early Recognition of Carcinoma of the Stomach, has appeared (Medical News, February 16, 1895). Dr. Stewart reviews Boas's work, and states that while as yet he is unprepared to offer the data obtained from an investigation of the subject to the present because of paucity of material, etc., he "may readily state that thus far his observations are all in support of Boas, and he has come to feel that much may be expected from this new diagnostic sign."

### ON THE TECHNIQUE OF USING ANTITOXINE.

By GEORGE CHAFFEE, M.D., BROOKLYN.

Having just dismissed a patient on whom antitoxine was used, and as the use of the remedy is about to become general, a few lines on technique may not be considered out of place. First of all is the selection of a reliable preparation. Next, a suitable instrument, which is a mammoth hypodermic syringe. A very good one is made by George
Ermold, No. 312 East Twenty-second Street, New York.

An ordinary hypodermic syringe is of no use whatever. The Ermold Antitoxin Syringe holds ten cubic centimetres, one ordinary dose of “No. 2 curative.” Repeat this dose in from ten to twenty-four hours, according to the severity of the case. From one to three cubic centimetres of No. 1 will protect. The administration of antitoxin is simply hypodermic medication on a very large scale. The serum being aseptic, the same precautions and general laws of antisepsis must be observed as in making any operation. If the operation is not conducted with proper regard for asepsis, trouble will follow, and the reputation of the remedy will be made to suffer by careless operators. The syringe should be taken apart, and, with the needle, sterilized by boiling for five minutes in a solution of bicarbonate of sodium. If the cap on the needle end of the syringe can be unscrewed, the cylinder may be filled by pouring the serum directly from the bottle. If this cap can not be unscrewed, I sterilize a china egg cup, into which I pour the serum for filling the syringe. The inside of the egg cups runs to a point and none of the serum is wasted. After the instrument and cup are sterilized I fold them in a fresh napkin or towel and place them in my instrument bag, ready to be taken to the patient’s home. The locality selected as the site of medication is either between the shoulder blades, on the breast, on the thigh, or on the gluteal region. On account of the large amount to be injected a place is selected over which the skin is quite free. The skin over the point selected should be cleansed with brush, soap, and water, and after this a solution of bichloride or permanganate of potassium. The size of the needle used and the amount of serum injected—ten cubic centimetres—make a local anesthetic quite necessary, especially with timid children. For many reasons I should object to the use of cocaine for this purpose. As an anesthetic I use a small piece of ice, with only one layer of napkin between it and the skin, held on the site of medication for about two minutes only. Upon its removal pour over the site a little more of the bichloride or potash solution, cold; pick up a fold of the skin at once, and pass the needle well in for about an inch, and inject very slowly. When the needle is removed, apply the tip of the finger for a minute; next apply cotton and collodion dressing to seal the puncture. The collodion dressing should be allowed to remain for two or three days, when it may be removed and a dressing of vaseline and cotton applied. Slight discoloration of the skin over a spot about an inch across will be found. Following is a brief clinical history of a case covering six days where antitoxin was used:

C. A., aged nine years, girl.

First Day.—10 a. m.: Pulse, 100; respiration, normal; temperature, 102°; small patch of membrane on each tonsil; severe headache.

Second Day.—Before using, 4 p. m.: Pulse, 108; respiration, normal; temperature, 107°; severe headache; great thirst; restless; back and limbs are stiff; membrane is spreading over tonsils; culture was made; ten cubic centimetres of No. 2 antitoxin. After using, 9 p. m.: Pulse, 90; respiration, 30; temperature, 105°. Thirst continues, but patient not so restless.

Third Day.—Before 11 a. m.: Pulse, 120; respiration, 26; temperature, 102°; breathing was heavy; had had a “bad night”; no headache; limbs are not stiff; membrane spreading, nearly covers both tonsils, but is thinner and lighter in color. Report from bacteriologist on culture shows Klebs—Loeffler bacilli. Five cubic centimetres No. 2. After 4 p. m.: Pulse, 112; respiration, 22; temperature, 101.2°. Patient slept for an hour after injection; not so much thirst; membrane is clearing from tonsils and forming on posterior pharynx. “Feeling better.” 9 p. m.: Pulse, 110; respiration, 22; temperature, 101.5°; quiet, bright, and easy.

Fourth Day.—Before 11 a. m.: Pulse, 106; respiration, normal; temperature, 99.8°. Patient is in good condition. Membrane is all off except a small speck on each tonsil. Collodion dressing removed from first operation. Vaseline and cotton applied.

Sixth Day.—Noon: Pulse, 94; respiration, normal; temperature, 99.8°. Membrane entirely gone. Collodion removed from second and third operations and dressed the same as the first.

Note.—On the eleventh and again on the twentieth day after the membrane appeared, cultures were made for the purpose of raising the quarantine earlier if possible. Report of examination still shows presence of diphtheria bacilli.

No. 226 West Forty-seventh Street.

SOLID RETROPERITONEAL GROWTHS IN CHILDREN.*

By CHARLES P. McNABB, M.D.,
Professor of Obstetrics and Diseases of Children, Tennessee Medical College, Knoxville, Tenn.

From the title of my paper it will be seen that all cysts and purulent collections of the retroperitoneum are excluded, and as tubercular deposits in the lymph glands of that region are not sufficient to cause tumor, I shall also pass that by without further notice.

Tumors springing from behind the peritoneum will usually prove to be renal and of connective-tissue or epithelial origin. To be sure, an occasional fibroma, lipoma, angioma, and lymphadenoma have been met with; so also do the curious congenital rhabdomyoma, composed of striped muscular fiber and sarcomatous tissue, appear at long intervals, while Lobstein’s cancer, or retroperitoneal sarcoma, will be seen in any long series of cases.

A very large percentage of abdominal tumors in children under five years of age will be cancer or sarcoma of the kidney, with the chances much in favor of the latter. Of cancerous growths, the most frequent is the ependymal variety, which reach the largest size, develop rapidly, and are often encapsulated. Sarcomata are sometimes encapsulated, but oftener not so, and are also of luxuriant growth. Either may be primary or secondary, but when primary they originate either in the fibrous stroma of the cortex or in the subnucous cellular tissue. Sometimes they start

* Read before the Knox, Tenn., County Medical Society at its stated meeting, January 24, 1895.
from a lymphatic gland or renal tissue at the hilum, and after penetrating the capsule take on and retain for a considerable time the form of the kidney by expanding its capsule.

Sarcomata are of the large and small round-celled varieties and are extremely vascular. Extravasation of blood into them is sometimes so great as to give them the appearance of a large blood clot.

The causes of malignant growths of the kidneys are renal calculi, pyelitis, retention of urine or pus in the pelvis or ureter, and mechanical injury; but in children the cause is often so obscure that the most diligent inquiry fails to find it.

The symptoms of sarcoma and encephaloid of the kidney are identical—tumor, pain, irritability of the bladder, progressive emaciation, steady increase in the size of the tumor, and bloody urine in a large percentage of cases, which, when it occurs, is more constant than it is with stone in the bladder and contains clots representing casts of the pelvis or ureter, which Osler says he has never seen in any other condition than malignant disease of the kidneys.

Late in the disease symptoms due to pressure on other organs appear—viz., edema of the lower extremities, dyspnea, rapid pulse, vomiting, and constipation. Uremia is said to be rarely if ever present, which is due, no doubt, to the fact that these growths are seldom bilateral.

The symptom of greatest importance is the tumor, appearing first in the ileocostal interval, then extending upward, downward, and toward the median line, bulging laterally and filling up the loin.

The colon, being anchored to the kidney, is always found in front of the tumor until displaced by the large size of the growth.

The pain differs from that of stone in not being increased by movement, is less boring or grudging, and is more daring or stabbing in character. The harder the growth the severer the pain; hence it follows that as encephaloid and sarcomata are the varieties met with in children, and as they are so soft as to be often mistaken for cystic growths, we are spared that distressing symptom in the majority of cases.

Hemorrhage may be profuse or absent altogether. The urine, if free from blood, is normal both in quantity and quality, cancer-cell tube casts and pus being rare if ever present.

The following case will, I hope, be of sufficient interest to justify me in reporting it to you:

Annie M.K., born November 29, 1891, was a bright, healthy infant, except for a few slight pulmonary and intestinal catarrhal attacks, which were of no consequence, until May, 1893, when she had an attack of continued fever of indefinite type, lasting about two weeks. From this fever her convalescence was slow and rather unsatisfactory, and she did not regain her former plump and ruddy appearance, although she was very bright and quite active in her movements, until September following, when she had an attack that resembled vesical calculi in its behavior. So strongly did the symptoms counterfeit stone in the bladder that three thorough soundings were made under chloroform with negative results. The urine was scant, strongly acid, of high specific gravity, and loaded with urates, which led me to the conclusion that there was probably calculi lodged in the pelvis of the kidney or in the ureter, but this conclusion was blended with the hope that instead of a calculus, the concentrated urine had produced and was aggravating a vesical catarrh. The salts of lithium were administered freely, plenty of water allowed, a bland diet suggested, and the bowels were kept open with saline, under which treatment the little patient's condition improved so much that she was dismissed in November, and, though not satisfied with her condition, I lost sight of the case for a few weeks, during which time the mother knew she was illing; but the symptoms were not pronounced, and, as I was overwhelmed with illness in my own family, she nursed her little one in silence and hoped for the better.

February 3, 1894, while bathing the child, the mother discovered a "lump in her left side" and called me in a few hours later. I found that the child had emaciated considerably since I had last seen her, but otherwise her general condition was fair. There was a tumor about as large as a goose's egg situated in the region of the left kidney and extending downward to the crest of the ilium and upward to the tenth rib. There was no bulging in the flank, but the growth appeared to touch the lateral lumbo-abdominal wall, and extended upward to within half an inch of the median line. It was ovoid in shape, was smooth, firm, and immovable. The abdominal wall could be lifted up over it, and the percussion note over it was tympanitic when the colon was empty and dull when the bowel was distended with feces.

From these circumstances I concluded that it was a retroperitoneal growth, and from its situation that it sprang from the kidney. There had been no hematuria—in fact, the urine was normal at the time, both in quantity and quality, and there had been no complaint from pain. Nephrydrosis was excluded by the firmness and immobility of the tumor and a diagnosis of solid growth involving the left kidney was made, and this diagnosis was supported by the able consultants that saw the case at various times—viz., Dr. William Delpeuch, Dr. B. B. Gates, and Dr. John M. Boyd, of this city. The absence of pain inclined me to the belief that it was sarcoma. The tumor grew rapidly, and the child emaciated pari passu with its growth until June 22, 1894, when death closed the unequal contest. The post mortem was made twenty-four hours after death: present and assisting, Dr. D. H. Williams, Dr. M. H. Lee, and Mr. R. E. McNabb.

An incision was carried from the manubrium to the pubes; the abdominal muscles were cut loose from their attachment to the ribs and turned back, displaying a large semi-fluctuating retroperitoneal tumor, filling the entire left side of the abdomen, and extending across the pelvic brim to the right linea arcuata. The colon was attached to its anterior surface, but pushed over almost to the median line. The small intestines lay altogether on the right side of the spinal column, and were empty, as were also the stomach and large intestine. The cardiac end of the stomach and the left lobe of the liver lay on top of, or anterior to, the upper extremity of the morbid growth. The pelvic organs were normal in all respects. The right kidney had undergone compensatory hypertrophy, but was perfectly sound, as was every other organ in the body; the left kidney had entirely succumbed to the ravages of the invader except at the pelvis, which contained a drachm of creamy pus, beneath which there was a little tissue of nearly normal appearance. There was not half an ounce of adipose tissue to be seen in the whole body, and yet the child had retained a morbid appetite to the last, and her digestion was perfect all the time. There was not a single morbid adhesion anywhere to
be seen, and not the slightest evidence of secondary involvement of any other organ.

The growth had insinuated itself around the iliac and renal vessels, but they had not invaded to any considerable extent, if at all, as there had not been the slightest oedema of the lower extremities.

The ureter was included in the tumor to within an inch and a half from where it entered the bladder. Nothing abnormal was detected in the visible portion.

The tumor was not weighed when removed, but very nearly filled a gallon bucket, and was supposed by the gentlemen present to weigh six or seven pounds. On section it presented a dirty-gray appearance and was of brainy consistence. It did not contain a drop of fluid except a drachm or so of pus in the pelvis, and there was no evidence of former extravasation of blood into its substance.

Sections mounted by Dr. Williams showed it to be of epithelial type. Ziegler says that encephaloid cancer may remain long confined within its capsule when it is invested with a capsule, but it looks strange to see so large a growth of alveolar type in close contact with so many other organs susceptible of invasion and surrounded by a field so rich in lymphatics without secondary involvement anywhere.

The family history of this case is entirely negative. No trace of malignant disease has been recorded as far back as such history can be traced. I believe the pyelitis found at the autopsy was the aetiological factor of first importance, and that it was of catarrhal origin, but might have been due to uric-acid formations in the pelvis of the kidney.

The prognosis is very unfavorable. Death usually occurs in six months, and may come in as many weeks. Treatment is palliative and surgical. Palliative treatment consists in supporting the patient's vital powers by proper attention to hygienic laws, nutritious food, with artificial enzymes if necessary, sufficient outdoor exercise when the weather is favorable, relief of pain by anodynes, and the control of hemorrhage, if troublesome, by the administration of astringents internally.

If the growth is encapsulated, its complete removal offers a possibility of cure, provided always that the operation is done before there are too many adhesions to contiguous viscera and blood-vessels. The attempt to remove such growths of considerable size and not encapsulated is impracticable and should not be undertaken.

The Death of Sir William Scovell Savory, Bart., F. R. S., is announced to have taken place on Monday, March 4th, as the result of a short illness. He was sixty-nine years old.

The Death of Mr. Charles H. Robinson, F. R. C. S. L., of Kingstown, Ireland, is stated in the Lancet to have taken place on Friday, March 1st, after two days' illness. The deceased was an occasional contributor to this journal.
Some of the Responsibilities of Dictionary-Makers.

In our issue for February 9th we criticised the wording of a bill that had been introduced into Congress having for its object the creation of a commission to inquire into the subject of the pollution of sources of water supply that might endanger the health of the people of more than one State. Our objection was to the use of the word develop in the sense of detecting. In the Journal for February 23d we printed a letter from Dr. Charles Smart, of the army, in which he avowed himself the framer of the bill and argued that his use of the word develop in it had been proper. This contention he fortified with definitions from Webster's Dictionary. Dr. Smart certainly has the dictionaries with him in this matter, but that only shows how fallible the lexicographers are. "The world is ever moving," says Archbishop Trench, "and language has no choice but to move with it." When Noah Webster, the master definor, made his dictionary the word develop meant precisely what he said it meant, but the world has moved since then, and in that sense the word may almost be said to have joined those which, to quote once more from Trench, have "wholly disengaged themselves from their etymologies." Development, as we understand it now, is a formative, almost a creative process. Nobody now seeks to "develop" his hat when he is about to take a walk. The dictionaries that are now in common use give the current meaning of the word, but, still in the bondage of etymology, they also give the old meaning in a way to lead the reader to think it still dominant or at least often employed. In this they are unquestionably wrong, and to them should the blunder be ascribed if this verbal anachronism creeps into our legislation.

By the way, another gross misuse of the word develop crops out every now and then in medical writing. It is not uncommon to find it recorded of a patient that, after having apparently started upon a favorable course, he suddenly "developed" pneumonia or some other untoward complication. Now, in no sense of the word did the patient "develop" the intercurrent disease; he did not even, to revert to the archaic, uncover, unfold, lay open, disclose, unravel, disentangle, or detect it; least of all did he cultivate and nurse it or bring it to its full growth; in short, he did not develop it. Let us try to strangle this abominable misuse of the word before it meets with undeserved recognition in the dictionaries.

Having thus blamed the lexicographers, we are doubly glad that we can conscientiously support them under what we believe to be an unjustified reproach put upon them by our esteemed contemporary the Medical News. "The dictionaries," says the News, "derive the compounds of ur- and of urin- from the Greek ὑπο-

MINOR PARAGRAPHS.

An Exceptionally Praiseworthy Instance of Professional Secrecy.

Whatever may be thought of Coroner Hoober's conception of the criminality of abortion, no conscientious physician can fail to applaud him for having recently suppressed the name of a practitioner suspected of complicity in a criminal abortion. It is time enough to give out names when a case of that kind actually comes to judicial notice. Grave hardship and most grievous notoriety have, as our readers well know, been in-
The Craig Epileptic Colony.

The utterly unreasonable and disreputable attempt to legislate Dr. Frederick Peterson and his associates from the management of the colony ought not to be tolerated in the Legislature. Dr. Peterson is virtually the creator of this beneficent institution, and to deprive it of its guidance now would be a deplorable step.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 19, 1895:

A Correction.—Dr. Ohlmacher, whose article entitled Some Suggestions in Bacteriological Technique appeared in our issue for March 24, asks us to say that the word "benzene" should have been printed benzine.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 10 to March 16, 1895:

Heizen, Charles L., Major and Surgeon, Fort Douglas, Utah, is granted leave of absence for one month, to take effect about March 10, 1895.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending March 16, 1895:

Young, L. L., Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Va., and to wait orders.

Fahrenholt, Ammen, Assistant Surgeon. Ordered to the U. S. Steamer Baltimore.

Society Meetings for the Coming Week:

Monday, March 25th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, March 26th: New York Dermatological Society (private); Medical Society of the County of Lewis (quarterly), N. Y.; Buffalo Obstetrical Society.

Wednesday, March 27th: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private), New York; Auburn, N. Y., Medical Association; Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society; Berkshire, Mass., District Medical Society (Pittsfield).

Thursday, March 28th: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

Births, Marriages, and Deaths.

Married.

Fischer—Robert.—In New York, on Wednesday, March 20th, Dr. Louis Fischer and Miss Clara Robert.

Died.

Bratenahl.—In New York, on Monday, March 18th, Dr. Gustav Weber Bratenahl, in his twenty-eighth year.

Fanning.—In New York, on Thursday, March 14th, Lenora Carpenter, wife of Dr. A. M. Fanning.

Forest.—In New York, on Friday, March 15th, Carrie Lucia, wife of Dr. William E. Forest.

Mowry.—In Allegheny, Pa., on Thursday, March 14th, Dr. Robert B. Mowry, aged eighty-two years.

O'Leary.—Near San José, Costa Rica, on Friday, February 8th, Dr. Jeremiah O'Leary, formerly of New York, aged fifty-two years.

Sampson.—In Tiffin, Ohio, on Monday, March 18th, Dr. W. G. Sampson, in his ninety-third year.

Skiff.—In Frankfort, N. Y., on Wednesday, March 13th, Dr. Perrin O. Skiff, aged sixty-eight years.

Smith.—In Meridian, Miss., on Tuesday, March 12th, Dr. A. H. Smith.

Obituaries.

Jeremiah O'Leary, M.D.

As is sentimentally recorded under the heading of Births, Marriages, and Deaths in this issue of the Journal, a New York physician, Dr. Jeremiah O'Leary, ended his earthly career in a distant country, Costa Rica, on the 8th of February. He was born in Ireland, but was brought to New York with his parents when he was a mere boy. He was a graduate of the medical department of the University of the City of New York, of the class of 1864. Soon after obtaining his medical degree, being too modest to launch out upon the practice of his profession, he entered the Pacific Mail Steamship Company's service as a purser, and it was on board ship that the editor of this journal, then a surgeon in the company's employ, first met him. A close attachment sprang up at once between the two youngsters and proved enduring. In 1865 they both served together as acting assistant surgeons in Annapolis. For certain short periods Dr. O'Leary practiced medicine in New York, but most of his professional career was spent in Costa Rica, and he married an estimable lady of that country. Two of his daughters, Mercedes and Marita, "the O'Leary sisters," are well remembered by many a New Yorker for their proficiency at the piano when yet hardly in their 'teens.

Jerry O'Leary—for it was by that endearing name that his friends all called him—was one of the most lovable men that the Lord ever sent into the world. He was utterly without guile. His career, which included a residence in Japan for a time, was not without stirring and even dangerous incidents and it was always beset with difficulties, but his unsuspicious and uncomplaining nature, full of benevolence toward all mankind, gave him a serenity that beamed amid all adversities and hardships. Peace to his noble and gentle spirit!

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of December 5, 1894.

The President, Dr. C. C. Barrows, in the Chair.

Empyema of the Antrum of Highmore.—Dr. C. G. Coakley presented two cases of this condition. They were interesting as illustrating both the chronic and acute forms. The chronic case was that of Mr. D’S, forty-five years of age, who had been sent to him by Dr. J. E. Winters. He had been taken sick on December 8, 1893, with a marked chill and a sharp rise of temperature. The elevation of temperature had lasted for two days, and then there had appeared an odorless, purulent discharge from the left nostril. Five or six days later there had been a marked odor to the discharge, and he had complained of very intense supra-orbital and occipital headache. Previously to his coming to Dr. Winters the nose had been washed out twice daily for four months by one physician and once daily by another physician for two months. Within a half hour or more after the washing the discharge had been as profuse as before—indeed, so profuse had it been that it had “saturated two or three Turkish towels every day.” On examination, the left nasal cavity had been found very much contracted, the inferior turbinate swollen so as to touch the septum, and the entire cavity filled with very foul-smelling pus. Examination with a probe had shown the inferior turbinate to be sound, but a necrotic condition of the middle turbinate. The test by transillumination had shown the whole affected side dark in the infra-orbital region, and also an absolute darkness of the pupil on the affected side. A triangular-bladed knife had been introduced into the antrum, along the floor of the nares underneath the inferior turbinate bone; yet on its withdrawal no pus had escaped. A second puncture had then been made, and a large quantity of extremely foul-smelling, thick pus had escaped. Not wishing to sacrifice a sound molar tooth, an opening had been made on October 13th, under ether anesthesia, through the canine fossa into the antrum. A probe passed into this opening had shown high up posteriorly a soft tumor of about the size of an almond. This had been cut loose from its attachments with a curette, and had been allowed to remain in the antrum. A silver tube had then been introduced for drainage and the cavity washed out, at first with a solution of permanganate of potassium, two grains to the ounce, and subsequently with peroxide of hydrogen, two or three times a day. On the fifth day the tumor—a polypus—somewhat shriveled and decomposed, had been washed out through the tube. The necrosed portions of the middle turbinate and ethmoidal cells had been removed by means of a special curette constructed to fit the narrow nasal cavity. Up to the present time some twelve curettages had been performed, with the result of removing nearly all the dead bone. The discharge from the antrum had practically ceased two weeks ago, but, as there was a slight purulent discharge from the nose, he did not feel it safe to remove the silver tube from the antrum as yet.

The other case—the acute one—was that of a gentleman, thirty-one years of age, who had been sent to him by Dr. T. J. Biggs. Three years ago there had been aching in a molar tooth on one side, and a dentist, in attempting to extract it, had broken it off. That night another dentist had “killed the nerve.” Since that time there had been occasional soreness, but by October 31st this had given place to severe pain. Then the entire tooth had been extracted. Two days later a purulent nasal discharge had begun on the same side, and the pain had been temporarily relieved. A needle passed by the patient up through the tooth socket at this time had revealed the presence of a collection of pus. On November 4th there had been such severe frontal headache as to incapacitate him for business, and the discharge had become foul-smelling. On examination, November 13th, there had been found marked swelling of the tissues in the left nostril, and these had been bathed in foul-smelling pus. The result of transillumination had not been so marked as in the other case, owing to the bones having been naturally thicker, but still there had been a fairly distinct difference in the illumination on the two sides. Under cocaine anesthesia a drill had been passed through the alveolus into the antrum and pus evacuated. No necrosis had been detected either in the antrum or nose. At the end of the tenth day the discharge had ceased. On the twelfth day the tube had been removed. Although the orifice through the alveolus had been still patent, there had been no discharge and the antrum had been empty.

Dr. Coakley also exhibited the special tube he had had constructed for the first case.

Dr. E. Le Fevre asked if in these cases there had been complaint of headache elsewhere than in the frontal region.

Dr. Coakley replied that in the cases he had seen there had been almost invariably complaint of pain over the outer half of the supra-orbital ridge. He had always looked upon this as a reflex pain from pressure, probably on the infra-orbital nerve. The occipital pain was possibly due to anemia or other secondary condition.

Dr. Le Fevre said that he had asked this question because some years ago a patient had been coming to him frequently for the relief of an occipital headache. The usual methods of treatment had been tried without avail. Finally the patient had come to him stating that there had been a discharge from the nose, and that with this there had been a great increase in the severity of the headache. Examination then had shown the antrum to be the seat of a supplicative process. As soon as the antrum had been freely opened the headache had entirely disappeared.

Dr. Joseph D. Bryant said that he would like to refer to two cases bearing upon pus collections in the antrum and oblitinate neuralgia. One of these patients had been a physician, who had had for many years a persistent neuralgia at the supra-orbital notch and in the superior division of the fifth pair. No history of any discharge from the antrum had been obtained, nor had there been any deformity at the time to indicate such a condition. It had been the fashion at that time to remove the supra-orbital nerve and destroy Meckel’s ganglion. He had opened into the antrum and pus had poured out very freely. The quantity of pus had astonished him in view of the fact that there had been no evidence of such an accumulation. Meckel’s ganglion had then been removed, notwithstanding the liberation of the pus collection. The patient had been heard from five years later, and had still continued to be free from his neuralgia. Subsequent experience had led the speaker to think that an exciting cause of the neuralgia in this case had been the pus accumulation in the antrum.

The second case had been that of an adult woman who, without any symptoms of pus accumulation in the antrum, had had a chronic and exceedingly severe neuralgia of the supra-orbital and supramaxillary region. An opening had been made into the antrum and a large quantity of pus evacuated. A favorable prognosis had been made in this case because of the fortunate experience with the other one; but in this second one he had been mistaken, for after a short time the neuralgia had re-
turned and had become so severe as to cause partial dementia. The chief interest in these cases was in the fact that the pus accumulations in the antrum had contributed to the neuralgia without manifesting their presence by external signs. In view of the fact that Dr. Coakley's patients had been so thoroughly syringed, he would say that it should be remembered that a continuous discharge of pus from the nostril without assignable cause, particularly if increased by change of position of the patient, should lead one to strongly suspect the presence of suppuration in the antrum.

In another case in which the antrum had been inflamed and the bone necrosed, the opening had been made in the canine fossa. The opening had persisted for eight years or more, although there had been no discharge for some time. He had seen it recommended to have a tooth put in on a plate so as to act as a plug to close an opening made through a rootocket of a tooth.

Dr. Coakley said that certainly some of these patients when allowed to go on did exhibit intense neuralgia, whereas many others seemed to become accustomed to the pain so that ultimately the only symptom would be the unilateral foul smelling discharge. This would often last for many months before coming under the notice of a physician, and then the necrosis of the bone would render the healing both difficult and tedious. He would like to emphasize the importance, therefore, of studying such cases well when a discharge of this character was present.

Dr. S. Dana Hubbard presented the following specimens:

(1) Ulcer of the Stomach.—An Italian, thirty-one years of age, of alcoholic habits, had been admitted to the hospital on October 12, 1894. He had been taken sick with fever and cough, and at a dispensary the diagnosis of measles had been made. He had been admitted shortly afterward to the Riverside Hospital, and at that time he had had an abundant eruption characteristic of measles. His face had been swollen so much as to resemble cyspechos. There had also been fever and delirium. Antipyretics and enemata had been given, and in a few hours he had been apparently in a much better condition. On the next day his bowels had become quite loose; he had had gloomy forebodings, and his pulse had become irregular. On the next day his temperature had remained above 102° in spite of antipyretic measures, and his delirium had become quite active. The bronchitis had improved, and the measles eruption had become less marked. Other physicians had seen the case, and had come to the conclusion that it was one of typhus fever, although the speaker had persisted in the original diagnosis of measles. The patient's condition had become rapidly worse on October 15th, and in the afternoon he had vomited some bright red blood, and had then quickly gone into collapse. A few hours later it had been found that the percussion note over the stomach had changed from tympanitic to dull, showing hemorrhage into that viscus. No urine had been excreted at that time for twenty-four hours. The hemorrhage had become quite profuse shortly after this, and at 9 a.m. the following day he had died. At the autopsy the stomach had been found filled with blood, and at the lower end of the esophagus had been three linear ulcers. One of these had been deep and extended down into the stomach. No previous history had been obtainable, but it had been surmised that he had been a “sword swallower.”

(2) Ulcer of the Ileum and Caput Coli; Typhoidal Case Mistaken for Typhus Fever.—M. N., a young Irishman of intemperate habits, had been delirious at the time of his admission, and had had a general mottled eruption. This had been at the time of an epidemic of typhus fever, and the case had been diagnosed by the board of health and by the hospital physicians as typhus fever. He had had a low type of delirium with more or less cyanosis; the eyes and conjunctive had been normal; there had been subsultus tendinitis, a dry, hot skin, and an eruption all over the trunk and both upper and lower extremities. This eruption had consisted of macules, disappearing on pressure, rather deeper than pink. The abdomen had been tympanitic, but not tender. The urinary examination had been negative. On July 11th he had been semi-conscious. On the following day the pulse had been very rapid and compressible, but there had been no new groups of eruption. He had died at 3.30 a.m. July 15th. The autopsy had shown several very large ulcers. Up to the time of his death it had been thought that the case had been unquestionably one of typhus fever, but, in view of the post-mortem findings, the speaker had been led to think it an irregular form of typhoid.

(3) Rectum in a Child obstructed by a Circular Membrane.—A child, two days old, had been admitted to the hospital with no history other than that there had been no movement of the bowels. The external appearance of the anal region had been natural, but on passing a catheter an obstruction had been met with at about an inch. The sphincter had been dilated with the finger, which had then encountered the same obstruction. The latter had appeared to be cone-shaped. On aspiration a dark fluid had escaped. This membranous obstruction had been pulled down with forceps and a small incision made into it. A large quantity of meconium had been discharged. The next day the child had died.

Ovarian Cysts.—The President presented two ovarian cysts. They had been removed from different patients last summer on the same day. Both of these cysts appeared to be dermoid in character. One of them had been removed from a young married woman, twenty-six years of age, who had been perfectly well up to eighteen months previously. At that time she had had an early miscarriage, which had been followed by more or less pelvic distress for about a year. She had then been seen at the Harlem Hospital, and had been subjected to an Alexander's operation for the relief of a supposed retroversion of the uterus. The operation had, however, given no relief, although when seen by the speaker the uterus had been found in excellent position. Examination had shown a tumor back of the uterus. This tumor had been removed by abdominal section. Undoubtedly the Alexander operation had been done with the idea of relieving a retroverted uterus, the tumor behind that organ having been mistaken for the retro-displaced fundus of the uterus. The operation, the speaker said, had given him an opportunity of seeing the condition of the internal organs after an Alexander's operation. He had been much pleased with the results of this examination, the shortened round ligaments, as seen from within, being more than sufficient to retain a uterus in its proper position. With more than forty successful cases of Alexander's operation on his list, the speaker had concluded that failures after this operation were due to its application to unsuitable cases.

Dr. W. Evelyn Porter said that the specimen just referred to was an excellent illustration of the importance of making a careful examination under anesthesia before performing any operation for retro-displacement of the uterus. Of course, the introduction of a sound might have cleared up the condition, but not necessarily. A careful examination under anesthesia, however, should reveal the true condition, even though there were thick abdominal walls and more or less adhesions. Efforts were being made by some to remove such growths through the vagina, and certainly those just presented would seem, from their nature and situation, to have been excellent cases for this method of operation. Personally, however, he did not advo-
cute the vaginal operation, because the mortality from abdominal section was already so low.

The President said he believed that the patient had had the tumor for some time, and that probably the presence of this tumor had induced the miscarriage. It was for this reason that he had stated so positively that the first operator had made an erroneous diagnosis, for it did not seem possible that the tumor could have grown there during the two months that had elapsed since the first operation.

(To be concluded.)

PHILADELPHIA COUNTY MEDICAL SOCIETY.
Meeting of December 12, 1894.

The President, Dr. De Forest Willard, in the Chair.

(Concluded from page 342.)

Tumors of the Brain.—Dr. Alfred C. Wood read a paper entitled Subcortical Glioma of the Cerebrum affecting principally the Amyl Center; Removal; Recurrence of the Growth; Second Operation. He reported the history of the case in the form of an abstract from a clinical lecture that Dr. H. C. Wood, in whose service at the University Hospital the patient had been treated, had delivered at the hospital in January, 1894.

The features of special interest in this case, Dr. Wood said, were: 1. The accurate location of the growth clinically. 2. The precision with which the tumor had been exposed by the trephine opening. 3. The immediate and complete left-sided paralysis, followed by perfect restoration of the normal condition in the face, and the return of a very fair degree of function in the leg, while motion in the arm had failed to improve decidedly, showing that the arm center had probably been completely removed, while the face and leg centers had been but slightly en- croached upon at the operation, and, although suffering tempor-

ally from the traumatism, had preserved their integrity. 4. The recurrence of the growth followed by its successful re- moval, the patient having remained well until the present time, seven months after the last operation and eleven months after the first. 5. The fact that the hemiparesis had not preceded the spasm and myotonia had been absent. It was maintained by Mills, Seguin, and others that both these conditions were to be noted in the subcortical lesions of the brain, and in a case recently reported by Diller and Buchanan the convulsions had been preceded by paroxysms.

The present position of cerebral surgery, the speaker said, marked one of the great achievements of the healing art, and had been made possible entirely through the agency of modern aseptic technique. We did not now consider it a more serious matter to expose and explore the brain than the peritoneum. Unfortunately, the affections of the brain were not so frequently suitable for surgical attack as those of the peritoneal cavity were. However, with the seat of numerous important functions of the brain already determined, with the constantly increasing certainty with which the neurologist was able to find definitely the exact seat of numerous pathological processes, with the ability to cut down upon and expose these points with precision by reason of a knowledge of cranio-cerebral topography, and with the present improved operative technique, the legitimate field of surgical interference must grow broader and broader. To-day it was not sufficient to rest with the diagnosis of a brain tumor, but, having determined its presence, it was incumbent upon the physician to extend to the patient the same opportu- nity for relief that would be granted him in other surgical affections.

It was evident that, in order to successfully remove a tumor of the brain without taking the life of the patient, it must be situated upon or near the convexity. From a careful study of the post-mortem records of six hundred cases of brain tumor by Starr (Brain Surgery, 1893) there had been found forty-six in which an operation had been indicated by the general and local symptoms, and in thirty-seven (six per cent. of the total num- ber) the conditions had been such that the tumor could easily have been removed. The average proportion of brain tumors that were favorably situated for removal, as given by various authorities from a study of post-mortem records, was seven per cent. It was especially interesting to note that in the cases ana- lysed by Starr the tumor could have been removed easily and with safety to the patient in at least 78-7 per cent. of those in which the symptoms had pointed to a growth in an accessible region. There was no doubt, however, that the number would be much greater in the future for the reasons already mentioned.

In regard to the mortality of these operations, he said, the same author, from a study of the operations so far reported, had found that, in a series of eighty-one cerebral tumors, the growth had been successfully removed fifty-four times; of these patients, thirty-nine had recovered and fifteen had died, the percentage of final recoveries being therefore 48-14.

As a result of his studies Starr had stated that the large major- ity of the gliomas and the glio-sarcomata had been infiltrated in the brain substance to such an extent as either to have escaped detection at an operation or to have been impossible of excision. When it was considered, said Dr. Wood, that this statement was based upon a study of six hundred cases, the one reported must be considered as having had an unusually successful termination.

The cause of these tumors was as obscure as that of those situated upon other parts of the body. In a large number of the cases a history of traumatism would be obtained, but whether or not this had any aetiological bearing it was impos- sible to say. The patient whose case the author had reported had received a blow on the head thirteen years ago. At the time of operation there had been no evidence of injury either to the scalp or in the skull.

Dr. J. Madison Taylor said that he was especially interested in this case. Recently he had had the opportunity of again ex- amining a patient who some time ago had met with an injury in a region similar to this. He reported the case four or five years ago. In his case there had been sensory phenomena connected with the opening in the skull which were absent in Dr. Wood's case. The patient, a boy, when two or three years old, had fallen and crushed the skull, and a spicule of bone had been forced down on the area occupied by the hand and arm centers. No harm had followed for two or three years, and then convul- sive seizures had begun and continued, and when he had reached the age of twelve or thirteen years there had been large epileptoid convulsions due to the pressure over the region mentioned. The point of bone had then been removed, and an opening of considerable size left in the skull. The opening was now about two inches in length and over an inch and a half in width. There had been no convulsive seizures since the operation. In this case there existed a morbid fear in regard to injury over this opening. Any touch or pressure caused a hide- ous pain like meningeeal headache, and it was impossible for the patient to lie on this side.

He would like to hear in the discussion some mention made of the possibilities of covering such openings. This seemed to him to be an important consideration.

In his case there were no motor symptoms whatever. The injury had been on the right side, and it was noticeable that the growth of the left side had not been so great as on the right. This was most conspicuous in the hand, which was half an inch
shorter than the right. The arm was somewhat shorter also than the right. In the legs no difference could be detected. There was no spasticity whatever, and the patient, now twenty-two years old, was a skilled mechanic of great activity and strength. The speaker thought it might be important to protect this open area in some permanent fashion, and trusted that he should hear of a proper means of doing so proposed by Dr. Wood, whose reputation as a surgeon justified his expectation that the latest and best devices would be used.

Dr. Charles S. Potts said that the case reported by Dr. Wood had been under his observation for a year before operation. There were two points of interest in regard to the local symptoms. There were two symptoms which had been advanced by different neurologists, the presence of which would tend to show the existence of a subcortical lesion. The first of these was the coming on of paroxysms before the convulsions. In several instances this had occurred. This had happened in a patient operated on by Dr. Diller, of Pittsburgh, where a subcortical cyst had been found, paroxysms having been present in this case several months before the occurrence of the convulsions. In the case reported by Dr. Wood this did not occur, the convulsions having preceded the paroxysms.

The second symptom was the existence of persistent tonic spasm of the muscles. Dr. Mills had reported two such cases, and had rather advanced the view that always in subcortical lesions we had this condition of tonic spasm. In this case nothing of the kind had been present, although the lesion was subcortical. Other neurologists had also advanced this view.

Dr. John B. Rogers said, in reply to Dr. Taylor’s question, he thought that, as a rule, no deleterious influence was exerted by these soft spots left by the removal of portions of the skull. They were usually closed by fibrous or fibro-cartilaginous tissue. He had, of course, seen a considerable number of cases where these soft spots had existed, and the pulsation of the brain could be seen, and, as a rule, the patient had had no special inconvenience. It was possible that neurologists might see a reason for the intense pain in Dr. Taylor’s case in pressure from entanglement of the dural nerves in the cicatrix. We sometimes saw cases where pieces of periosteum or dura, or both, were entangled in healed fractures of the skull. He had once trephined for traumatic epilepsy where there had been a large fiber of tissue connecting the dura with the periosteum. It was possible that in Dr. Taylor’s case there was some condition of this sort, the nerves being pinched by the cicatricial contraction of fibrous tissue.

Of course, as all surgeons know, we did put pieces of bone back. Such, however, was not the practice where trephining was done for intracranial pressure. In such cases the button of bone was left out so as to permit of expansion of the cranial contents. Where he removed a portion of bone for epilepsy it was not his practice to put the bone back. He had put the bone back under other circumstances, and there had been permanent closure of the opening. There was no reason why, in a case like Dr. Taylor’s, if the symptoms were sufficiently serious, an attempt should not be made to form a new cranial vault by the introduction of aseptic portions of bone from the lower animals, or from a skull which was trephined at the time. He knew of one case where a little cup of thin gold had been set into the skull after the removal of a good deal of tissue after fracture. The wound had closed over this little cup of gold and healed by first intention. He thought that celluloid had also been used for a similar purpose.

The President remarked that the experience of surgeons with regard to the removal of bone was that when it was desirable to relieve pressure the button of bone was left out. The condition of this man was probably more favorable than if the button of bone had been replaced. In cases where there was no reason for leaving the bone out, and it could be kept in position, it afforded a good protection and was likely to live.

Dr. Woon said that the questions asked by Dr. Taylor had been fully answered by Dr. Roberts, with whom he agreed fully in ascertaining the pain in Dr. Taylor’s case to implication of nerves in the cicatrix. He had had the opportunity of examining a number of cases at varying periods after the operation of trephining, but had not met with such a condition, or with any disadvantage which had resulted from not replacing the portion of bone removed. Dr. Potts had referred to this case as one of subcortical tumor. The speaker believed that the growth had been subcortical in its inception, but that at the time of operation it had been found to have infiltrated the cortex also.

A Face Guard for Examination of Infectious Throats.—Dr. J. Madison Taylor presented a simple device for protecting the operator’s face while examining the throats of those who were suspected of diphtheria or other contagious disorders, and said that it served a good end very practically. There was constant need in dispensary work among children to deliberately and fully explore the throat, and during this process much splattering of mucus and saliva occurred, which flew in the direction of the physician or of the nurse, and might well be spared them. In making the needful applications to diseased parts, too, this could be done more quietly and thoroughly if the face was protected. The chief value of the guard, he said, was that it enabled us to secure material for bacteriological research, which often required some judgment in selecting the precise area from which to take it. An assistant could best hold the guard, made of plain glass, in a thin metal frame, or the mother could do so. The size was small, just enough to cover a face, and not too large to carry in the ordinary small instrument-satchel used by physicians. The glass slid out of the frame readily for thorough cleansing, or the whole could be laid in a sterilizing tray.

Meeting of February 12, 1895.

Some Therapeutic Uses of Acetanilide.—Dr. Oscar H. Allis read a paper entitled Acetanilide versus Quinine to Treat Chills and Fever, and Acetanilide as a Dusting Powder, by Dr. Benjamin H. Brodnax, of Brodnax, La. In 1890 Dr. Brodnax had first used acetanilide in a case of catarrhal fever with convulsions, in an infant nine months old, with astonishing amelioration of all grave symptoms in fifteen minutes. His next trial of the drug had been in intermittent fever in a family of three small children. The doses had ranged from two to three grains, and when the time for the chills arrived the children were asleep and perspiring. He had employed the drug quite extensively, but it was especially in chills and fever that he desired to emphasize its great merit. His mode of using it was as follows:

If there was time before the chill, he gave from a grain and a half to two grains of calomel in quarter-grain doses half an hour apart. Then, whether the bowels had acted or not, he gave, according to the age, from two to six grains of acetanilide twenty minutes or half an hour before the expected chill. Gentle perspiration, with sweet and natural sleep, usually promptly followed the administration of the drug, from which the patient wakened entirely relieved and ready to go about in half an hour.

When there was no time before the chill to administer the calomel it might be deferred until afterward; but the acetanilide could be given immediately before or during any stage of the chill or fever, with the happy result of promptly inducing sleep and gentle perspiration. Should the desired effect of the drug—viz., sleep and perspiration—not follow its administra-
tion within half an hour, a second dose of equal amount should be given.

The after-treatment consisted of the use of an acid tonic, such as a solution of eighty grains of sulphate of iron in a dilution of dilute hydrochloric acid. This should stand for twenty-four hours. Ten drops, in water, should be given three or four times a day.

The author had now treated several hundred cases of chills with acetaminide, and without quinine, and reported his success in the hope that others would be induced to give it a trial.

Acetaminide and boric acid, in equal parts, as a dusting powder, he had used extensively in ulcers, burns, etc.

He found the powder especially serviceable in the excoriations of infants and febrile people; with it he dusted the funis of the newborn babe, while over the vulva of the mother he placed a little cotton previously well dusted with the powder. Made into a paste with glycerin, he had used acetaminide in a vaginal tampon to allay ureteric pain. In the case of a woman, sixty-one years of age, almost crazed with the itching from a pustular eruption that covered the lower part of the abdomen, the vulva, and the anus, the powder well dusted over the affected parts after first moistening them with dilute carbolic acid, had produced six hours of consequent sleep.

She had been wakened by a return of the itching, and, rising, had washed the parts and reapplied the dilute carbolic acid and powder, and had immediately gone to sleep again. A great improvement had been observed the next day, and in a few days the parts were well.

Previous to the application of the powder she had not slept well for several nights even with the aid of morphia.

Internally he had used acetaminide to correct a foul breath, also in dysentery and diarrhoea. When taken on the tongue and held in the mouth a few moments before swallowing, it had the effect of allaying the distressing thirst that accompanied the fever.

Dr. J. M. Andes claimed it seemed strange at this time that any one would assume to have obtained better results from the use of acetaminide in malarial intermitents than from the use of quinine. Unfortunately, Dr. Brodnax did not offer any experimental facts upon which to base an opinion of the mode of action of the acetaminide. The well-known antiseptic action of the drug was the only explanation that he could offer. He believed that Dr. Brodnax was a careful and reliable observer, and did not question the fact that cases of chills and fever had been cured after even single doses of acetaminide. Although we had entered upon days of scientific therapies, he did not think that the days of rational empiricism had entirely passed away.

We knew that quinine cured chills and fever. Since that discovery nothing had been brought forward that would supplant quinine in the treatment of that disease. It was not impossible that such a remedy might be found; possibly Dr. Brodnax had found it in acetaminide. The speaker had met with cases of malarial intermitents in persons in whom there was an unpleasant idiosyncrasy against quinine. Now, in such cases, a better substitute for quinine than those we had at present would be welcome and of great advantage.

The question whether or not there were objections to the use of acetaminide might be asked. The statement had been made that acute dilatation of the heart sometimes occurred in intermitents. Now it was known that acetaminide was a cardiac depressant, and in toxic doses had produced death by paralysis of the heart. While he did not consider this a bar to the use of acetaminide in the doses prescribed by Dr. Brodnax, he thought that this influence made it necessary to guard the heart during the time of its administration. If subsequent experience supported these observations the profession and members of this society should give a vote of thanks to Dr. Brodnax for a new remedy for malarial disease and one which promised to rank as a specific.

Dr. J. A. Cantwell’s experience with acetaminide in the treatment of disease had been, in two hundred cases or more, of skin eruption, especially intertrigo and eczema. He believed it to be the antiseptic that we were looking for in the place of iodoform. It had none of the irritating qualities that iodoform had, and in fact a great many cases of iodoform irritation had been cured by it. In cases of very moist skin disease it acted as a drying powder and also as an astringent. In other cases, like zoster, it acted well, dried up the eruption, and apparently stopped the disease; at least, it had seemed at the time as if acetaminide had produced this action.

Dr. G. G. Davis said that nobody would be gladder than himself for a satisfactory substitute for the foul-smelling iodoform. Combinations had been brought forward of boric acid and other substances with iodoform. The mixture of boric acid he preferred to the pure iodoform. The boric acid broke up the lumps which the iodoform contained and made it a more manageable substance as a dusting powder. He had also used acetaminide by itself, but had been unable to persuade himself that it was the equal of iodoform for surgical purposes.

Dr. Edward Martin had used acetaminide in about a thousand cases of suppurating wounds, and his experience was in those cases that it was superior to iodoform. It was less toxic, for one thing. It was very common among surgeons to observe in slowly healing wounds dressed daily with iodoform certain nervous symptoms, headache, and so on, indicating iodoform poisoning. This was not seen from the use of acetaminide; the wounds kept perfectly dry, there was no pus, and, of course, no odor, and the dressings kept as clean as with iodoform. He should continue to use it, he said, in place of iodoform.

Dr. Davis thought that the direction of surgical progress as regarded the application of powered antiseptic substances in recent wounds was on the decline, and he had no doubt that both iodoform and acetaminide would eventually be much less used than at present. Dr. Habtest, of Baltimore, made an application of silver leaf take its place. Of course, drying powders would always be used in the treatment of suppurating wounds.

Miscellany.

Cycling as a Cause of Heart Disease.—The Lancet for March 2d contains an abstract of a paper on this subject which was read by Dr. George Herschell at the Eighth International Congress of Hygiene and Demography in Budapest. The chief danger of cycling, he says, is the fact that a cyclist takes much more exercise than he is aware of, and is very frequently tempted to overtax his powers. The commonest way in which the cyclist injures himself is in climbing hills. When he is nearing the top of the hill the heart is dilated with the strain put upon it by the increased arterial tension. If the rider stopped at this point to recover himself, no harm would be done; but in too many cases, as there are only a few more revolutions of the wheel to carry him to the top, he redoubles his exertions, putting further strain upon a heart already taxed to the utmost limit of its capacity, and in those few moments damage has been done to the heart from which it perhaps cannot recover. The effects of the strain of excessive cycling upon the heart may be divided, says Dr. Herschell, into four groups: 1. Simple hypertrophy of the heart. 2. Acute dilatation of the heart, ending either in recovery, if the cause is removed, or in death if it
MISCELLANY.

3. Chronic valvular disease of the heart. 4. Functional derangement of the heart.

Simple hypertrophy of the heart is apt to occur in well-trained riders who do a great deal of cycling, and may be looked upon as a compensatory effort of Nature to enable the work to be performed. Cycling for extended periods of time at a great pace, like other forms of prolonged muscular exertion, enormously increases the blood pressure in the arteries. Hypertrophy of the heart follows the law which governs all muscles—that increased work is followed by increased growth if the nutrition is kept up. Moderate degrees of hypertrophy are quite compatible with health, and are usually unattended with symptoms. The danger, however, is in the ultimate effects which are liable to ensue. The heightened blood pressure in the arteries gradually produces a hard, inelastic condition of their walls, which perpetuates and increases the hypertrophy. Moreover, these altered arteries are prone sooner or later to undergo degenerative changes, and, having lost their normal elasticity, to give way on some occasion of sudden strain. As a rule, the athlete enjoys vigorous health for the few years during which he is actively working, and his heart is only enlarged enough to meet the constant demands upon it; but when the cyclist, no longer in his first youth and unable to compete with younger men, relaxes his efforts, his heart is now too large for the work it is required to do, and the symptoms of hypertrophy soon make themselves felt. Hypertrophy following overexertion may disappear under proper treatment, if taken early and the cause removed, but when it has persisted for a number of years this is rarely, if ever, possible, and ulcerous changes are apt to ensue. It is well known that athletes are liable to rapid deterioration of health when they relinquish their active exercises.

It is also probable that an hypertrophied heart may undergo degenerative changes while in active daily work. This is rendered probable by what is known to happen in the case of file-cutters, whose work consists in quickly flexing their biceps. The effect of this is to cause hypertrophy of that muscle, but after a few years it atrophies. This is so certainly known in the trade that file-cutters receive very high wages, based upon the probable working life of their hypertrophied biceps. It is possible that in this way we may have an explanation of the well-known fact that compensatory hypertrophy of the heart can not be preserved indefinitely, although the valve lesion may be stationary. Hypertrophy of the heart produced by cycling may terminate in one of these ways: 1. Recovery. 2. Valvular disease and disease of the aorta. 3. Degeneration of the heart muscle.

Acute Dilatation of the Heart.—Until the individual first shows signs of being "out of breath" both ventricles are sending equal quantities of blood into the pulmonic and aortic systems respectively in equal periods of time. At each beat the left heart is withdrawing from the lungs exactly the same quantity of blood that has been forced into them by the right heart. And it is evident that the oxygen supplied to the blood is exactly equal to what the body requires. Respiration and the heart's action, although hurried by the exercise, are carried on normally and without unpleasant sensations. If, however, the exercise is continued, the heart is stimulated to contract at such a rate that the respiratory muscles can not keep pace with it. Besides, the time during which it is possible for the blood to come into contact with the oxygen in the lungs is shortened.

"Shortness of breath" is thus produced, the sensation being, as we all know, the cry of the blood for more oxygen. Accompanying this will be obstruction to the circulation through the lungs, and a small abnormal amount of residual blood will remain in the right ventricle. If the extreme muscular efforts are continued the excess of venous blood in the pulmonary ves-
sels will increase with every beat and the right heart will rapidly dilate. At this stage the quantities of blood thrown out from the two ventricles are unequal. The heart continues beating and expelling the whole of its contents with the exception of the residual blood in the right ventricle. At last a moment comes when from fatigue the muscles at the base of the ventricles are no longer able to adapt the ring to which the bases of the valves are attached, so that the valves will efficiently close them. And since the whole of the valvular ring is expanded while the valves have retained their former size, regurgitation must take place. If at this point the individual ceases his muscular efforts, in all probability the heart will quickly recover itself; but if the recovery is not complete there may remain permanent incompetence of the tricuspid valve. On the other hand, if the exertion is kept up, the heart, being unable to pass on the whole quantity of blood that reaches it at each beat, undergoes rapid dilatation of the right ventricle and death by asystole is the result. Of such a character doubtless are the cases of sudden heart failure which has occasionally caused the death of riders even in the course of a journey. The following fatal case of acute overstraining of the heart occasioned by cycling came under the author's notice in 1884, and the notes may be of interest as showing the symptoms which may be expected. A man, aged forty-six years, had lately taken to cycling and used a heavy tricycle. After having followed the sport for three weeks and made some short journeys, he attempted to ride from Brighton, where he resided, to London, a distance of fifty-three miles. Dr. Herschell was called to see him about seven o'clock in the evening at his hotel and found him cyanosed and very exhausted. There was intense dyspnoea, and his pulse was 144 a minute and very feeble. His heart's action was irregular and weak. Pulmonary extended transversely from a quarter of an inch outside the right parasternal line to the left mammary line. The apex was beating in the sixth intercostal space in the left mammary line. A systolic bruit was apparent both over the mitral and tricuspid areas, and there was pulsation in the veins of the neck. The urine contained a trace of albumin. Unfortunately, in spite of treatment, he gradually sank, and died early next morning. The author was informed that the patient had never previously exhibited any symptoms which pointed to heart disease. The absence of marked hypertrophy of the heart would also negative the supposition. No post-mortem examination could be obtained. The case was evidently one of acute dilatation of the heart in a man not so young as to be able to undertake with impunity such a muscular task as a ride of fifty-three miles against time. The overstrained and distended heart was unable to contract vigorously enough to restore the equilibrium, and fatal syncope was the result. Acute dilatation of the heart produced by cycling, then, he says, may terminate either in recovery or in the production of valvular disease.

Chronic Valvular Disease of the Heart.—Dr. Herschell believes that the mechanism by which permanent valvular disease of the heart is produced by overstrain from exercises such as cycling is twofold: 1. As a sequel to acute dilatation of the heart. The ring, to which the bases of the auriculo-ventricular valves are attached, having been once stretched sufficiently to allow regurgitation to take place, does not recover itself, but remains permanently enlarged. We shall thus have regurgitation into the auricle. The patient will then pass through the usual stages of compensatory hypertrophy, with probably final breaking down of compensation. 2. As a result of hypertrophy. It is probable that the constant high tension in the arterial system, with the resulting strain upon the valves, occasions slight injuries to their surface with the subsequent production of sclerotic changes. In cases which had come under his notice he had
found that the great majority had suffered from lesions of the aortic valves, and he laid reason to believe that the hypertrophy always antedated the valve mischief. This, he says, is only what we might expect. The aorta, unlike the heart, can not strengthen itself against an excessive strain, as its activity is Practically nothing more than the recoil of elastic tissue. Strain of such a structure will cause chronic endarteritis and loss of elasticity. If we examine such an artery with a microscope we shall find small points of endarteritis upon the inner coat and patches of diffuse granular exudation in the middle one. The next step will be dilatation or pouching of the aorta just above the valves which are as yet competent. Many cases come under observation in this condition, and the following may be taken as a typical example: A man, thirty-one years of age, attended the author’s out-patient service at the hospital in the autumn of 1892. He complained of palpitation and shortness of breath. During the summer he had been constantly riding the bicycle, going on an average sixty miles a day for three days a week. On examination, there was evident hypertrophy of the heart, the apex beating in the anterior axillary line. The right margin of the cardiac dullness was half an inch to the right of the sternum. The arterial dullness over the upper edge of the sternum was decidedly wider than it should be, pointing to dilatation of the aorta. There were no bruises and no thrills, but there was marked accentuation of the aortic second sound. This would probably be the first stage in the production of valvular disease. As regards the further course of such a case there are, says the author, three possibilities: 1. The aortic ring may be stretched by the pouching of the aorta, and regurgitation may take place. 2. A valve may actually give way. 3. Sclerotic changes may take place in the valves. In any of these cases the disease will follow the usual course of valvular trouble produced by other causes.

Functional derangement of the heart as a result of cycling, he believes, is much commoner than is generally supposed. In many cases it is slight and the patients recover quickly, so that they are overlooked or the trouble is ascribed to other causes. “Irritable heart,” which was a term applied by Da Costa to the chronic tachycardia observed among the men who were engaged in the civil war, is a condition, says Dr. Herschell, which resembles in many respects the functional affections of the heart which are seen as the result of strain from cycling. It is extremely probable, he says, that they are identical as regards pathology. He believes that these conditions always follow a temporary dilatation of the heart in the following manner: It has been shown that right-sided dilatation of the heart is invariably produced by the prolonged strain of too rapid cycling. This dilatation having subsided when the cause has ceased to operate, the heart remains irritable from the stretching that its muscular fibers have undergone. It would seem in these cases, he says, as if the inhibitory function of the pneumogastric nerve was suspended, for when the heart has so far recovered itself from the immediate effects of the strain that the pulse rate has fallen to normal, any slight exertion or emotion will bring the palpitation on again. The symptoms which the author has observed in these cases are the following: 1. Palpitation of the heart, which is very distressing, and usually occurs on the slightest exertion or emotion, and, if not relieved by proper treatment, may possibly end in the permanent establishment of a “rapid heart.” 2. Shortness of breath, which usually accompanies the palpitation, and comes on after the slightest exertion. 3. The sensation of sinking at the epigastrium. In certain cases, says the author, this has been one of the most prominent symptoms. 4. Subjective sensations in the region of the heart. The patient is conscious of the heart’s action, and often feels as if it were going to stop. 5. Intermittency of the heart’s action. In several cases the author believes that he has traced the origin of this condition to a temporary dilatation of the heart as the result of hill-climbing. 6. Anginoid symptoms. Two of the author’s patients complained chiefly of pain in the cardiac region, coming on in paroxysms, running down the left arm, and accompanied by a feeling of suffocation and impending death.

These, then, says Dr. Herschell, are some of the possible evils of excessive cycling. On the other hand, there is the undeniable fact that in moderation and under proper conditions it is one of the most health-giving forms of exercise. In established heart disease, strange as it may seem, it is one of the most potent remedial measures. Beginning with the lowest gear for the shortest periods, and on level roads, carefully graduated cycling is able to establish that compensatory hypertrophy which alone can enable the victims of valvular disease of the heart to live in comfort. For this reason the author recommends it. With regard to the preventive measures and precautions against the dangers of this fascinating sport, the author lays stress upon the following points: 1. The use of a low gear, which has been described in another part of the paper. 2. The upright posture in riding. The stooping posture, so common among the modern cyclists, by contracting the chest prevents the proper expansion of the lungs, and by interfering with the aeration of the blood causes the condition of breathlessness to come on more quickly. 3. Proper food when riding, and the avoidance of muscle poisons, such as beef tea. It is probable that the digestive powers of the stomach are inhibited during riding, and from this it follows that the ordinary food taken on the road is not digested, and does not provide the cyclist with energy. Dr. Herschell advocates the use of peptonized gruel or soup. 4. The cyclist must avoid preparations of kola and cocoa. These, by numbing the sense of weariness, enable the rider to do injuriously excessive work, almost without his knowledge. 5. On no account should the cyclist continue riding after he has begun to feel short of breath, or when there is the slightest sensation of uneasiness in the chest. This simple precaution is one which can not be too earnestly recommended.

The Treatment of Diphtheria with the Antitoxine made at the Pasteur Institute.—In the March number of the New York Therapeutic Review there is an article on this subject in which the writer remarks that the universal interest manifested by the medical profession in the antitoxine treatment of diphtheria has prompted him to give further information as to the mode of preparing the new therapeutic agent at the New York Pasteur Institute. The first thing to be considered, he says, is the selection of the horses which are to produce the antitoxine. Every animal is thoroughly examined by Professor A. Littauard, of the American Veterinary College, who rejects every horse showing any trace of organic or contagious disease. The horses are then placed in the college hospital and are inoculated for the purpose of discovering whether they show any action denoting the presence of glanders or tuberculosis. In connection with this subject, says the writer, it is interesting to note that on an average three or four out of every ten horses subjected to these inoculations are rejected, showing that glanders is perhaps a commoner disease than has hitherto been suspected. The horses that have been found to be in perfect health after these rigid tests are placed in stables of which the stalls are thoroughly washed and disinfected every day. The cultures employed are filtered for the purpose of obtaining the toxine, but before this is done they are examined under the microscope, and if they contain other bacteria than those of diphtheria, they are rejected, as an association with other microbes might produce different and dangerous toxines,
After a horse has received a number of injections, both into the veins and under the skin, and ceases to react to the effects of large doses, its serum is tried upon guinea-pigs. If the power of immunity against a mortal dose of toxine is found to be too weak, further injections are practiced upon the horse until the degree of the power of immunity becomes satisfactory. As to the efficacy of the serum and the conscientious way in which it is prepared, says the writer, an investigation of the results obtained by the physicians who have made use of it is the only criterion of value.

It is the intention of the institute to supply the strongest antitoxine obtainable, stating the strength and allowing physicians to vary the dose according to the age of the patient and the severity of the disease, rather than to supply it in various degrees of potency.

While it has been impossible, says the author, to hear from all the physicians who have used the antitoxine, the many letters published in the same number of the *Review* and those taken from other journals make up a valuable contribution to the literature of this subject. These letters, he says, mention sixty-two cases with only one death. While the author does not for a moment assert that such an extraordinarily low mortality is sure to occur under the use of the antitoxine, the severity of many of the cases shows the excellent results that may be expected. Other cases are mentioned where the serum was injected most successfully for the purpose of conferring immunity upon children and adults who had been exposed to infection.

The writer refers to an article which appeared in the *Boston Medical and Surgical Journal* for January 24, 1895, in which Dr. F. G. Morrill, of Boston, relates that three outbreaks of diphtheria occurred at the Children's Hospital, and on each occasion admissions had to be suspended. Every patient in the hospital, regardless of the malady for which he was under treatment, was subjected to an injection of five cubic centimetres of the serum prepared by the Pasteur Institute, and then admissions were continued with the condition that each child should be subjected to an injection. Not a single fresh case occurred. Three nurses and thirty-nine children were injected for immunity, and the ill effects were unimportant. Of the nine children injected for diphtheria, two of the sickest ones sat up in bed and enjoyed themselves in twenty-four hours after receiving a dose of fifteen or twenty cubic centimetres. All the other children did well with one exception. In another number of the same journal Dr. Kenelm Winslow reports four cases of diphtheria in which the patients improved wonderfully, as regarded both general symptoms and local lesions, after the use of the antitoxine, which had been employed on the first day of the disease. Dr. Winslow also speaks of the occurrence of urticaria in some of his cases, and appears to object to the statement made by the institute that no local reactions follow the use of the antitoxine. This statement, says the author, is absolutely true as regards septic and inflammatory reactions due to impurities contained in the preparations. The occurrence of urticaria and erythema taking place in a number of cases has been observed by Roux and by the German physicians, and there is as yet no means known of preventing its occurrence in a certain proportion of cases. The possibility of its taking place is always present, but certainly cannot be considered as a contraindication to the use of antitoxine. Between probable death and possible erythema, says the writer, the choice should easily be made.

The Pasteur Institute furnishes antitoxine to the provincial board of health for the province of Quebec, where it has been used with good results. In New Orleans a commission composed of some of the ablest physicians began to investigate the matter from the first. The commission has employed the antitoxine in over a hundred cases with very good results.

The institute, therefore, says the author, may congratulate itself upon the fact that the long period of preliminary work is over, and that the treatment of diphtheria has resulted in a lower mortality than has hitherto been observed.

**An Anecdotc of the Late Dr. Oliver Wendell Holmes.**—In the *Boston Medical and Surgical Journal* for March 14th we find the following letter from Dr. S. L. Abbot, of Boston:

> "An excellent paper on Microscopical Reminiscences, by Dr. Palmer E. Cole, published in the *New York Medical Journal* of February 23d, contains many pleasant recollections of Dr. Oliver Wendell Holmes and pays a well-deserved tribute to his great interest in the microscope, and his ingenious invention of various useful adjustments to it in those early days of its use by the medical profession. He also quotes a passage from his last letter to him, in which he says:

> "My most successful contrivance was a stereoscope of a very simple pattern, which had a great run, and has remained popular, I think, to the present time."

> "It is well, I think, to remind your readers that this little invention, the hand stereoscope, is one of Dr. Holmes's contrivances, as I dare say many of them, of the younger generation of doctors, are not aware of the fact. I myself have found it a very great convenience."

> "Dr. Cole's paper tempts me to give you a reminiscence of my own, which fully illustrates Dr. Holmes's bonhomie and at the same time his honest self-appreciation."

> "In my early student days in the Tremont Street Medical School, after a recitation in anatomy to Dr. Holmes, at which I happened not to be present, he sang to the class a new song of his own composition—probably one of his humorous medical productions, but of this I am not quite sure. Two days after, while he and I were engaged together in the dissecting room, I casually remarked, 'I greatly regret not being present at the last recitation in anatomy.' "Why?" he asked. 'Because I lost the song you were so kind as to sing to the students.' After a moment's pause, with his head turned down a little toward one shoulder, and a peculiar compression of the lips—an attitude and expression of the mouth which all his old friends will remember—he said abruptly, 'Would you like to hear it?' "Why, of course, doctor," said I, 'no one could hear it without liking it.' "Well, I'll sing it to you," was his immediate reply. So he laid down his scalpel and forceps, and standing facing me, with the poor relic of humanity on the table between us, he began, and went through the whole of it, with as much enthusiasm as if he were singing to a thousand people. After the prolonged applause of his audience of one had subsided, he said, 'Do you like it?' "Why, of course, doctor," said I, 'no one could hear it without liking it.' "Well," said he, 'it is good. No one but a fool would pretend he doesn't know when he has done a good thing.'"

**The New York Academy of Medicine.**—At the last general meeting, on Thursday evening, the 21st inst., the special order was to be a paper on Disease of the Eye Dependent on the Gripe, by Dr. Thomas R. Pooley, and one entitled Diseases of the Ear Dependent on the Gripe, by Dr. Edward B. Dench.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 28th inst., a paper entitled Total Extermination of the Uterus by Abdominal Section will be read by Dr. Ernest W. Cushing, of Boston, and Dr. Grace Peckham-Murray will read a paper the title of which is to be announced. Cases will be reported and specimens and instruments exhibited.

**The Ohio State Medical Society.**—The fiftieth annual meeting will be held at Columbus on May 15, 16, and 17, 1895.
Original Communications.

AN APPARATUS FOR WASHING OUT THE STOMACH AND SIGMOID WITH A CONTINUOUS CURRENT, WITH RETURN STOMACH OR RECTAL TUBE.

BY JOHN C. HEMMETER, Ph.D., M.D., etc., BALTIMORE.

In making known a new instrument or apparatus for the mechanical treatment of gastric and intestinal diseases, a brief abstract of the history of the stomach tube may perhaps not be out of place. That it is a comparatively recent instrument may be gathered from the despising remarks of Th. Frerichs (article Verdanng, Wagner's Handworteub. d. Physiol., iii, Abth. i, S. 789, published 1842-1853): “The disturbances of the gastric secretions,” he says, “and the instances that bring them about, constitute a domain that has been very little investigated. There is little hope of seeing this subject, which is so important for the pathology of digestive diseases, cleared up in the near future, because insurmountable difficulties are in the way of obtaining digestive material in man.” It was reserved for the versatile Kussmaul to overcome the insurmountable difficulties of Frerichs (quoted from Martins and Lattke, Die Magensäure, Stuttgart, 1892). He demonstrated in 1866 (Kussmaul, Ueber d. Behand. d. Magenwärterung durch eine neue Methode, m. d. Magenpump, Deutsch. Arch. f. klin. Med., 1869, Bd. vi, S. 455) that the stomach pump—which Dr. Wyman had invented, and had first been used by another pioneer American physician, Dr. Bowditch, for the evacuation of empyema—made it possible to obtain the contents of the human stomach at all times without difficulty. It is certain that the stomach pump was recommended for removal of stomach contents in diseased conditions prior to Kussmaul—for instance, by Lefèvre in 1842 (Martins and Lattke, Die Magensäure), and, according to Leube (Die Magensäure, 1879, Erlangen), also by Camstutt in 1846. But the extensive use of the instrument was caused by the practical proceedings of Kussmaul, only for therapeutical purposes, however.

The first one to employ the stomach tube for a purely physiological investigation was Szabo (Szabo, Beiträge zur Kenntniss der freien Säuren d. menschl. Magensaftes, Zeit.-schrift f. physiol. Chemie, 1877-78, Bd. i, S. 140), who analyzed in Hoppe-Seyler’s laboratory the gastric contents of a patient from Kussmaul’s clinic, having removed them for this purpose by a stomach tube. The first one to use the tube for establishing a diagnosis between gastrectasia with and without carcinoma ventriculi was von den Velden (von den Velden, Ueber Vorkommen u. Mangei d. freien Salzsüure im Magensaft bei Gastrectasia, Deutsch. Arch. f. klin. Med., Bd. xxii, S. 369).

Up to the time of Ewald’s suggestion of substituting a soft rubber tube—gas hose, as he called it—for the hard one (Ewald, Virchow’s Archiv, ci, 1885, S. 330: Anwendung eines weichen Gummirohres als Magensonde), now about ten years ago, all stomach tubes were made of inelastic, non-compressible, hard silk rubber. They had to be inelastic, since they were intended for use with the pump only. These tubes were not free from danger, and cases were reported in which the gastric mucus was torn away and brought up with the stomach contents.

In this period falls the introduction of enlarged Nélaton rubber catheters as stomach tubes by Leube (Leube, Die Magensäure, Erlangen, 1879). Not long after, the dangerous pump was replaced by a method of siphoning with the help of a funnel, according to the plans of Th. Jägersten, L. Rosenthal, Hodgen, and others. This soft elastic stomach tube, with a rubber funnel attached to it, answers all practical purposes; particularly true is this in case we simply desire to make a quantitative or qualitative analysis of a test meal obtained by Ewald’s expression method. But in obstinate cases of chronic gastritis, in gastrectasias from various causes, with advanced decomposition of gastric contents, it is often a matter of half an hour to an hour before the stomach can be siphoned clear. With a view to more effectively carrying out lavage and shortening the time it requires, Ewald and Rosenthal advocate the use of an irrigator placed above the head of the patient on a shelf. To the outer end of the stomach tube is attached a Y-shaped glass tube, one arm of which is connected with an elastic tube running to the irrigator, while the other arm is connected with the discharging tube. Through the irrigating tube water runs into the stomach, the discharging tube being compressed by the fingers. When the patient feels the distention, the tube from the irrigator is closed by pressure of the fingers; the vertical tube discharging from the stomach is opened by releasing finger pressure, and the organ is emptied. By repeating this the organ may be filled and emptied as often as desired. (See Ewald, Diseases of the Stomach, English translation, p. 65; also William H. Welch, article on Dilatation of the Stomach, Pepper’s System, vol. ii, p. 604, both with illustrations.)

The instrument to be described in the following accomplishes all that Rosenthal’s apparatus does, without using alternate pressure on discharging and irrigating tube. In this new method water runs into and out of the stomach continually through one and the same tube.

The apparatus consists, first of a large glass jar (Fig. 1), $a$, having a stopcock, $f$, near the bottom, graduated into divisions, each indicating one hundred cubic centimetres, and placed on an elevated platform, shelf, or the like. Secondly, of a double or return stomach tube, which differs from the ordinary stomach or lavage tube of Ewald by the presence of a partition of soft rubber running through its entire length and seen in cross section at $l$, really dividing the instrument into two canals, $b$ and $c$. The canal for the inflow, $b$, connected at $f$ with the faucet of the reservoir bottle, is only half of the caliber of the outflow canal, $c$ (this is not very apparent in the accompanying drawing)—a most important provision to insure at all times a greater facility to the outflow than to the inflow, otherwise the stomach may become overloaded with water, which, owing to the elevated position of the reservoir, runs into the stomach very read-
HEMMETER: APPARATUS FOR WASHING OUT THE STOMACH. [N. Y. Med. Jour.,

ility and in greater quantities than could be carried away by an outflow tube of the same size as the inflow tube. The connecting piece, \( k \), with its four branches, \( r r r r \), is made of hard rubber to prevent any stretching of the two tubes, \( b \) (inflow) and \( c \) (outflow), at \( h \), the junction. The end of the return tube has side openings, \( p p \), in addition to the openings at the lower end, which does not terminate abruptly, as in the sketch, but is beveled off smoothly and tapers, as shown at \( m \).

In case the apparatus is to be used for washing out the rectum and sigmoid, the patient must be placed in the position suggested by Dr. Howard A. Kelly for atmospheric distention of the female bladder and rectum (American Journal of Obstetrics, vol. xxix, No. 5, 1894; also vol. xxx, No. 1, 1894). In this position the double rectal tube depicted in Fig. 2 is slowly introduced, consisting simply of the smaller soft inflow tube, \( i \), united with the larger outflow tube, \( o \), and separating at \( a \), not ending bluntly, as shown in cross section at \( b \), but tapering, as shown in Fig. 2 at \( c \). The gastric tube is useful in cases of considerable gastric decomposition or accompanied with great masses of mucus and requiring much time with the single tube. The inflow and outflow can be controlled by the pressure of the fingers of the patient if necessary. The same precautions are necessary with this as with the single tube in its employment. The double rectal tube is very useful in membranous colitis. With Dr. H. A. Kelly’s method I have frequently succeeded in exposing the entire rectum and the first turn of the sigmoid flexure to view in direct sunlight. It is possible to pass a very soft rubber rectal tube of my pattern entirely through the sigmoid flexure into the descending colon in the cadaver. But it must be done before rigor mortis sets in, the subsequent rigidity rendering it impossible. In order to pass it through the sigmoid in the cadaver, the rectum must first be cleaned, the subject inverted so as to have gravity favoring the tube, and when the first turn of the sigmoid is reached the water is started to run from the inflow tube. This will keep pushing away folds of mucous membrane and excrement and facilitate the successful passage of the tube.

From these results on the cadaver it is conceivable that we may yet be able to pass a tube into the transverse colon in the living subject.

During March, 1894, I had under my observation a medical practitioner who learned to use the double rectal tube on himself without difficulty. He had shown symptoms of membranous colitis at intervals for three years. When the attacks were severe they were accompanied by intense rheumatic pains in the left shoulder and running down the left arm. For these rheumatic pains he had treated himself for a year by various remedies usually considered useful in rheumatism and neuralgia, but with temporary relief only. I suggested to him that his pains were perhaps due to the absorption of toxic substances from the colon and sigmoid, and advised regulation of diet, rest, and washing out of the colon. He informed me that he has had no return of the rheumatic pain since May, 1894 (I heard from him on January 10, 1895, the last time), but that he is in the habit of washing out his colon once a week. He asserts that purging does not afford him a complete relief of his intestinal and rheumatic symptoms. During July, 1894, he was traveling for recreation, and, not being able to use his rectal tube in the hotels, on railroads, etc., he tried to keep his colon as clean as he could by the use of purgatives. During this time he felt a return of the rheumatism in his left arm. On his return home the rheumatic pains again yielded to lavage of the colon.

In concluding this communication I wish to emphasize that double or return stomach tubes have been made before the one described herein was brought out, but so far as I know they were made of hard, inelastic material and were found to be of no practical utility. I inquired at instrument factories of all of the large eastern cities without success, not having found any mention of a double or return stomach tube in literature of the subject. A surgical mechanic who had visited the last Paris International Exposition stated that he had seen such tubes there, but they were very short, inelastic, and as hard as the old tubes formerly used with the pump. It is possible that what he described is a return catheter for the male bladder. The return stomach tube is 1 3 centimetre in diameter and can be ordered of any desired length; the double rectal or sigmoid tube is 2 3 centimetres broad one way, and 1 5 centimetre in the direction at right angles to the first measurement.

1734 Linden Avenue,
THE PLASTER OF PARIS, WOOD, ALUMINUM, AND OTHER SPINAL SUPPORTS.*

By A. M. Phelps, M. D.

I am exceedingly obliged to Dr. Sayre for the courtesy which he has extended by asking me to discuss the paper of the evening. On nearly all of the points which have been raised in this paper I fully agree with him. And that the plaster-of-Paris corset is one of the best supports for Pott's disease of the spine I have never doubted. Without it it would be difficult for me to conduct the clinics and dispensaries of which I now have charge. While it has many defects and merits, its good qualities will more than overbalance the bad, and because of this, and because its application is based upon accurate scientific principles, I give it a most hearty indorsement.

I have used the plaster-of-Paris corset from its very first inception. I have watched its growth from the time of its first application; I have seen it fail through bad materials and worse application; I have seen it bitterly fought against by its opponents, receiving just and unjust criticisms. I have watched its methods of application gradually reconstructed, the materials from which it is made improved, and I am free to say, after fourteen years of experience, that it is one of the best supports to be used in Pott's disease of the spine the world has ever seen. The arguments which have been urged against its use are most fallacious. That it does not support is argued by some of its bitter adversaries. But when in Pott's disease of the spine a patient is suspended and a jacket properly adjusted, he is at once relieved from a condition of pain and suffering, and to that extent that any amount of pressure upon the shoulders does not produce pain. I am convinced that something does support. If it is not the jacket, what is it? A patient with lateral curvature of the spine is suspended; a plaster corset with lacings is made to fit him in this suspended and straightened position. After the corset has been adjusted the patient is three inches taller than before its application. If the corset does not support, what makes him three inches taller? I have personally observed this change in many cases, and no amount of argument advanced by the opponents of the plaster-of-Paris corset can possibly disprove a clinical fact. One fact is worth more than a thousand theories. The first book written on steam navigation by an Englishman, in which he attempted to prove that a steamship could not cross the Atlantic Ocean, was a failure, because, after his book was printed, it was brought to this country by the first steamship. And so it is with this argument. The patient is three inches taller with the corset than he is without it. What makes him three inches taller? Support. It is true that this corset becomes filthy; vermin invade it; but it is inexpansible, and can be changed, if necessary, once a month. Much better this than the application of a steel brace that a mother or nurse can remove at liberty, handling the child in such a manner as to produce trauma and injury to the diseased vertebra. The steel braces must be frequently removed or else exorciations will occur. They excoriate and are uncomfortable if they give support, which is one of the strongest arguments against their use in Pott's disease of the spine.

We are all agreed, I believe, that the best orthopaedic machine ever devised is the human hand; guided by intelligence, it applies forces for the correction of deformity more delicately and perfectly than any inanimate object ever invented. Plaster of Paris is applied to the deformity. While in the plastic state the hands mold it to the corrected position, and hold it there until it is hard or set. Can you not see that now the plaster of Paris continues to do the work exactly as the human hand did it? In other words, plaster of Paris is effective as a brace or support only in proportion to the amount of gray cerebral matter concerned in its use. In the absence of the latter it is worthless. Proper materials must be used, else the plaster will not set rapidly. 

I. B. Clifton & Company make me a perfect hospital erinolino, No. 100, containing just the proper amount of sizing and no indigo. The White Dental Manufacturing Company, of New York, puts up the plaster in tin cans hot from the oven. These two materials make, when put together properly, a perfect bandage that will set in five minutes. This rapid setting of the plaster is necessary, because the hand holds it to the corrected position of the deformity. This material, with the stockinet sold by Ford, completes the materials necessary to make a perfect corset. The erinolino costs six cents a yard, the plaster of Paris three cents a pound, and the stockinet thirty cents a yard. A corset for a child six years old should weigh not to exceed one pound and a quarter, and for an adult two pounds and three quarters. This makes a support as light or lighter than the steel brace, and it supports as the steel brace can not.

What the profession wants is a proper brace—one that will apply extension and relieve pressure, and also act as an antero-posterior support, transmitting the weight of the body through the transverse and articular processes, thereby relieving the bodies of the diseased vertebrea. Such a support is to be found in the plaster-of-Paris corset; it removes from the nurse or the mother the possibility of interfering with the dressing. By its particularly broad, even surfaces, if properly applied, it does not excoriate, and can be worn for one or two years with comfort. Springing or bending the corset antero-posteriorly makes it an antero-posterior support. Thus we see that it combines the good qualities of all the steel braces that have ever been devised, and one more, and that is extension for the relief of pressure. The corset is heavy when improperly made. It is not so porous as we are led to believe. Its thickness makes it objectionable to women. This has led me to substitute for it the wooden corset (Fig. 1); the paper corset, made from paper such as is used in making paper boats; and the aluminum corset (Fig. 2). These corsets combine all the good elements of the plaster-of-Paris corsets, and, in addition to these, lightness, durability, and thinness, which do not interfere with the clothing of women.

In clinical work and among the poor patients the plas-

* Prepared to be read before the New York Academy of Medicine, January 31, 1886, in the discussion of Dr. Sayre's paper published in the Journal for March 16th and 23d.
ter of Paris corset fills the gap that nothing else can possibly fill. These patients, supported by steel braces, I am informed, and I have observed, almost invariably go on from bad to worse as regards deformity; they certainly do in disease above the eighth dorsal vertebra. I feel satisfied that in this class of patients the steel braces will be utterly abandoned in the very near future; they certainly should be in lateral curvature of the spine in any case. Now, in private practice, I know of no better dressing for Pott’s disease than a light and thin plaster corset during the acute stage, after that the corsets that I have already mentioned, the use of which will be found to be more comfortable and agreeable to the patients. The difficulty with leather corsets is that they fail to support, because they do not retain their shape; as a boot changes on one’s foot, so will a leather corset change upon the body. The spinal support for Pott’s disease of the spine must be unyielding and firm. The paper corset first made by Vance is, in some respects, a good corset; but it is not desirable; it is difficult to make, and it is somewhat expensive. Since the time of Vance other paper corsets have been made according to different formulæ; but they are made of paper and are really only modifications of Vance’s idea. The corset made by Weigl, of Rochester, N. Y., from the paper pulp used by printers in making their matrices, he alleges, is durable and comfortable. The corsets made for me by Horace Waters & Co., of Troy, N. Y., after the paper-boat formulæ, have proved most satisfactory; but it is more bother to get them than I care to endure. Other corsets made in this city, similar to that made by Vance, are open to the same criticisms as those mentioned. The jury mast and corset, when adjusted so as not to lift the head, but to draw it backward so as to transmit the weight of the head through the transverse and articular processes, makes the most efficient dressing that I know anything of, and particularly in upper dorsal and cervical disease. So far as I have observed, the deformity does not increase, as is the case with a steel apparatus in diseases of the upper dorsal region.

Professor Sayre has accomplished much by his constant and indefatigable hammering at the profession toward introducing the idea of partial suspension and fixation in Pott’s disease of the spine; but the idea of partial suspension and fixation in Pott’s disease of the spine carries us back almost to the traditions of medicine. Ambroise Paré, in 1579, used a fixation apparatus made from steel which is almost identical with the aluminum corset which I am using.

In 1696 von Nuck made a suspension apparatus which has been in almost constant use in Europe since that time. It is very similar to that used to-day bearing the name of the distinguished author of the paper of the evening. In 1700 Heister devised an antero-posterior support which in principle is the same as Taylor’s brace used to-day. It has been in use in England since that date. In 1754 Hauermann made a modification of von Nuck’s suspension apparatus, which seems, however, to be more a change of material than principle. In 1764 Levacher devised the jury mast, which was attached to a corset made of steel and canvas, and was used precisely as the jury mast is used to-day. Portal, in 1772, slightly modified the jury mast, but attached it to a corset in the same manner. In 1825 De La Croix still further modified it by adding the chin piece. Heine, in 1832, still further modified Levacher’s jury mast by adding a chin piece and attaching it to a steel hip-band corset. These jury-mast suspensions, taken together with the description of their use, are identical with those in use at the present time. About the only thing that this generation can claim in regard to spinal supporting is in the change of materials, using the principles laid down in the last century and the beginning of the present. They have been in constant use since then, and also the principles, as exemplified here to-night. I believe them to be correct. The profession owes a debt of gratitude to the author of the paper for having forced upon the American profession the idea of partial suspension and fixation in the treatment of Pott’s disease of the spine.

I offer the aluminum corset not as a substitute for many of the braces and corsets now worn in the acute forms of Pott’s disease and lateral curvature; I suggest it, rather, to take the place of such braces in cases requiring permanent bracing, or in individuals who are desirous of securing a support at any time which combines durability with lightness and comfort. So soon as a case of lateral curvature has been arrested, or the greatest amount of benefit has been derived from treatment, the aluminum corset will then be found a most agreeable permanent support. The aluminum corset has these qualities to recommend it to the patient:

1. Lightness.
2. Durability.
3. It is thin, and does not interfere with the form and clothing.
4. Being extensively perforated makes it the coolest and most agreeable of supports.

5. The patient can wear it during bathing.

An ordinary corset weighs from one to two pounds, depending upon the size. To prevent cracking and to protect it from perspiration, it is covered with a waterproof enamel which is applied by heat.

The steps of its construction: Make a plaster form of the body; send this form to the foundry and have a cast-iron anvil made; polish this, and then at a certain temperature the workmen will bend on to it two sheets of aluminum representing the two lateral halves. The frequent heating and hammering, together with the cylindrical shape, make the corset almost as strong as steel. The two halves are hinged in the back and closed with automatic clasps in front, which stop at any notch to accommodate itself to the body before and after eating. This corset completes my armamentarium in cases requiring spinal supports—viz:

2. The wood corset for lateral curvature and cured or convalescent cases of Pott’s disease.
3. The Beely corset for mild forms of lateral curvature, particularly in girls.
4. The aluminum corset for permanent bracing.
5. The celluloid corset which, in a way, takes the place of the aluminum.

I visited Dr. Waltuck, of Odessa, Russia, in 1888, and from him personally I learned the details of making the wood corset (Fig. 1) after several days of hard work. I found that Professor Lorence, of Vienna, had been using the corset for some time, and was much pleased with it. At that time, however, many of their corsets proved to be inefficient on account of errors in their construction. We have used the corset constantly since that time, and, with the modifications which we have made, it is one of the most efficient, comfortable, and suitable braces that I know of.

It has been with the greatest difficulty that we have succeeded in getting the proper materials for constructing the corset, and even now it is cheaper and better to import the wood from Vienna. The spruce timber which grows there makes a better shaving than any timber that we have attempted to use which grows in America. It is tougher and works better with the glue.

An impression is made of the body with plaster bandages. This mold is filled with plaster of Paris, which makes a perfect cast of the body. The corset is now made over this cast. The cast is changed somewhat in shape to make the form even straighter than the body in the suspended position.

Corsets made according to the method followed at the time I observed the process were not so perfect as they should be. The slightest excess of glue, moistened by the perspiration of the body coming in contact with the shirt or the skin, was exceedingly disagreeable. The perforations in this corset weakened it and allowed the glue to exude during perspiration.

To obviate all this I had the corset perforated, as seen in Fig. 1, in which perforations eyelets were punched. A special machine facilitates the perforating and the punching of the eyelets. The lacings are stitched on, as in Fig. 1. Trim the top and bottom with kid. The entire corset is covered inside and outside with two or three coats of shellac, which render it impervious to moisture, the eyelet holes ventilating it perfectly. The improvements which I have made in the corset consist in coating it with shellac on the inside and outside and putting eyelets in the eyelet holes, which add to the strength of the corset and ventilate it perfectly.

An ordinary corset for an adult weighs from a pound to a pound and a half. They are very durable, very comfortable to wear, and thus far I believe they are the best spinal braces yet devised.

I will add, by way of parenthesis, that the corsets, when completed, can be covered with silk or with stockinet, or they can be left in the linen finish.

THE TREATMENT OF LARYNGEAL TUBERCULOSIS
BY THE
APPLICATION AND SUBMUCOUS INJECTION OF CREOSOTE.

DESCRIPTION OF AN AUTOMATIC LARYNGEAL SYRINGE
FOR MAKING SUBMUCOUS INJECTIONS.*

BY WALTER F. CHAPPELL, M.D., M.R.C.S.,
SURGEON TO THE THROAT AND NOSE DEPARTMENT OF THE MANHATTAN EYE AND EAR HOSPITAL.

The success attained in the treatment of tubercular deposits of joints, glands, and other tissues stimulates the belief that were it possible to subject tubercular disease of the larynx to the same effective methods, equally favorable results might be obtained. The history of the treatment of laryngeal tuberculosis has, however, been of a most discouraging character. Morell Mackenzie, speaking on this disease, said he considered it practically incurable. At present the general feeling is that a more favorable prognosis may be given, and by a judicious selection of treatment the distressing symptoms may be considerably relieved and in some cases a cure effected. The most satisfactory results in this direction have recently been claimed from the use of strong solutions of lactic acid and curing the laryngeal mucous membrane. It has not been my good fortune to obtain the marked improvement from this line of treatment which has been reported by a few observers. I think it is not unlikely that further experience may prove that, in view of the possibility of a general reinfection following the use of the curette, it should be reserved for the ulcerative stages of tubercular laryngitis.

Creosote administered internally has probably proved more satisfactory than any other single drug for the treatment of pulmonary tuberculosis, its beneficial action being largely due to the presence of the cresote in the respiratory channels through which it is for the most part eliminated. The astringent, sedative, and antiseptic action of the cresote lessens cough and expectoration, and, according to

* Read before the Section in Laryngology of the New York Academy of Medicine, February 27, 1895.
some authorities, diminishes the number of tubercle bacilli. Although the improvement from creosote is conceded to be chiefly the result of its local action, treatment of tubercular disease of the larynx by the application of creosote has not received much attention, only a few observers having suggested it as an adjunct to internal administration. I have been unable to find any reports of creosote being given by submucous injection for its local action in laryngeal tuberculosis. I wish to bring before the Section this evening some patients who have received the creosote treatment by internal administration, topical application, and submucous injection. There is no pretense that the results from its use excel other methods of treatment, but I think an examination of the patients will lead us to agree that the combined uses of creosote give greater benefit than its internal administration alone, and, furthermore, that it compares favorably with any of the present methods of treatment.

Alcoholic and aqueous solutions of creosote are unsatisfactory, as they do not combine readily, nor do they diminish the irritating and pungent qualities of the creosote. Oily solutions are much to be preferred, as they greatly modify the unpleasant character of the creosote and, owing to their tenacious properties, cling to surfaces and spread a thin film over them which is not readily dislodged. By this means creosote may be kept in contact with mucous membranes for a considerable period and given ample opportunity to permeate the subjacent tissues to a variable extent. Castor oil is especially serviceable on account of its thick, viseid, and tenacious properties. It is also the most satisfactory solvent of creosote. The preparation of this solution requires considerable care, and a combination which may be generally employed consists of—

<table>

<tr>
<td>Olei. ricini</td>
<td>2 ij</td>
</tr>
</tbody>
</table>

The wintergreen and castor oil should first be mixed together, then the hydrocarbon oil added, and lastly the creosote. Sterilizing the solution by dry heat gives it a much clearer appearance. Mr. Huthenm-‘on, of the drug department of the Manhattan Eye and Ear Hospital, has also made me a solution containing one drachm of creosote to the ounce; but he informs me that it does not combine in any other than these two proportions with these oils. This oily solution of creosote is clear, very fluid and non-irritating, of pleasant odor and taste, and may be used as a spray, or applied by the laryngeal applicator or as a submucous injection. Topical application alone may be relied on for the successful relief of the symptoms of primary tubercular deposits with infiltration and hypertrophy of the mucous membrane, provided the temperature is not high and the general condition is good. If, on the other hand, the evening temperature is high and the case seemingly progressing to active ulceration, a few submucous injections should be used as adjuncts to local treatment. The cough, laryngeal soreness, and moderate dysphagia of primary cases are quickly relieved by sprays of creosote, but resolution of their infiltrations and hypertrophies is not so rapid. In several of my patients the laryngeal distress was relieved after a few applications, but the infiltration continued for months.

**Methods of applying Creosote Solutions Locally.**—The interior of the larynx should be thoroughly cleansed before any treatment is undertaken. Applications may be made by means of down sprays, the laryngeal syringe, or by absorbent cotton on an applicator. The latter is not a favorable method with the writer, as it occasionally produces an undesirable amount of coughing. An eight- or a ten-percent solution of cocaine saccharate is carefully applied to the larynx, this preparation being preferable, in my opinion, to the muriate, as it does not produce so much gagging. After the cocaine has had time to produce moderate anesthesia, a spray of creosote (two drachms to the ounce) is used. After the spray the pyriform sinuses may be filled with creosote solution, and also some of it allowed to drop into the trachea through the opening of a gum elastic tip which is drawn over the cannula of the automatic syringe described later. This keeps the laryngeal surfaces bathed in creosote for a considerable period, and the patient should, if possible, be kept perfectly quiet and not allowed to talk or swallow for half an hour afterward. The stronger solution of creosote may be used every third or fourth day and the weaker ones every day or so, depending entirely on the amount of stimulation it produces. I have seen the laryngeal membrane become very red and considerably swollen from too frequent applications. In the ulcerative stages of laryngeal tuberculosis, sprays of a drachm of creosote to the ounce can be used daily with advantage; but if there is no ulcerative process a personal experience of each case must decide the frequency of the applications. A slight burning sensation follows the applications of creosote solutions, but it only lasts a few minutes. The disagreeable taste is pretty effectually covered by the wintergreen oil.

In tubercular laryngitis with ulcerations, both topical applications and submucous injection should be employed. They hasten the separation of sloughing tissue, stimulate healthy granulation, and at the same time arrest progressive ulceration. The injection should be as superficial as possible, as the primary tubercular deposit is immediately beneath the epithelial layer. Weak solutions of cocaine may be sufficient in some cases, but complete anesthesia is usually necessary, and I have found twenty per-cent solutions to be the most satisfactory. They should be administered on an applicator, although it might be safe to employ the spray if the physician was well acquainted with his patient.

**Method of making the Submucous Injection.**—A long needle with a laryngeal curve can be used with any hypodermic syringe; but there are some drawbacks to this, as the movement of the hand in pushing down the piston is apt to make the patient gag, and conceals from view the point we wish to inject.

To obviate this I have had an automatic syringe made, as shown in the cut, which allows the operator to disengage the piston with his thumb and still keep the point of the syringe in view in the mirror.
CHAPPELL: CREOSOTE IN LARYNGEAL TUBERCULOSIS.

March 30, 1895.

The shank of the needle is a hollow tube about six inches long, which may be given suitable curves for laryngeal work. The needle is about half an inch in length, and corresponds to the large-sized hypodermic needle, with the opening close to the point.

The depth to which we desire to introduce the needle is regulated by a small piece of solid rubber ligature which is drawn over the needle and may be shortened or lengthened accordingly.

The rubber casing on the needle makes it easy and safe to employ pressure, and, owing to its suction, the rubber clings to the mucous membrane and prevents the creosote solution from welling up around the needle after the injection. The barrel of the syringe is partly glass and partly metal; the latter contains a spiral spring which is attached to the piston, and a longitudinal opening on the side of the barrel is notched to receive the catch of the spring. The piston goes the entire length of the syringe, and is graduated and furnished with a set screw to regulate the number of drops injected. The solution for injection may be warmed or not. The glass barrel should be filled and the piston catch pushed into the top notch of the metal barrel. The laryngeal needle, being already sterilized, is screwed on to the syringe and the piston dropped to the second notch of the barrel, thus filling the needle.

After regulating the set screw for one drop (which is the amount usually employed), the syringe is ready for use. It should be passed into the larynx with the right hand, under the guidance of the laryngeal mirror held in the left.

The point selected for the injection will of course depend on the situation of the tubercular deposit, and with a little experience any part of the larynx can be reached without much difficulty. When the point of the needle has punctured the mucous membrane, the catch of the spring is dislodged with the thumb, without changing the position of the hand, and the piston springs down as far as the set screw and makes the injection. If possible, the needle should be held in position for a few moments. Little pain or reaction follows the injection of oily solutions, but pure creosote causes a burning sensation and considerable soreness, which lasts a variable time. Much depends on the locality of the injection; the posterior surface of the arytenoids seems to be specially sensitive. There is little or no haemorrhage after the needle is removed, and the following day the mucous membrane is more tense and possibly somewhat redder. This condition subsides in the course of a few days, leaving the tissues in a wrinkled condition, as though the mucous membrane was too large for the subjacent parts. This is most noticeable around the arytenoids. Careful judgment is required to determine how often the injections should be made, but as a rule it can be done once in five or six days. If ulceration is proceeding rapidly, one injection may be given daily until three or four have been administered. This number would usually include the amount of tissue involved and promote its more rapid resolution and stimulate granulation. After several injections, it is well to wait for a time and see if the circle of resolution will not spread from the point of injection to the neighboring tissues.

The experience obtained from the comparatively few cases I have seen is, of course, not sufficient to allow of definite rules being made for the position of injections. It would seem, however, that some remarks about injections in different locations might be made.

The ventricular bands usually require superficial and deep injections, the former to reach the deposits in the bands, and the latter the ventricles of the larynx. The interarytenoid space should be treated from below upward, otherwise it would be impossible to obtain a good view after the first injection. Very superficial puncture should be made in the mucous membrane covering the arytenoids, as it is an easy matter to start a parichondritis in this situation. A row of injections should first be placed around the base of the arytenoid cartilages and gradually approach their tips. Tubercular infiltration of the epiglottis renders it so thick and firm that it is capable of bearing considerable pressure and is readily subjected to this treatment. A single row of injections may be made around the free border of the epiglottis about half an inch apart. The lingual surface of the epiglottis is very accessible for injection, but the laryngeal surface is not so easily reached. If the anesthesia is complete the epiglottis may in some cases be pulled forward sufficiently by the shank of the needle for the injections to be made. If this can not be effected, the needle may be pushed through the cartilage from its lingual surface.

A little experience will enable the operator to judge the thickness of the epiglottis, and the length of the needle we desire to use can be regulated by the rubber tubing, as already described. After the injections the larynx should be kept as clean as possible, and sprayed every day or so with the weaker solution of creosote.

In primary cases of laryngeal tuberculosis it is not necessary to keep the patient in bed; but in the ulcerative stage, with high temperature and general muscular weakness, it is better to have him remain in bed and under observation for twenty-four hours. In Case III an injection into the vocal cord produced considerable cough, and embarrassed the respiration to a slight degree for a few hours. Just why this happened I am unable to state, as many other injections in the cords of the same patient did not produce any similar results; neither has it happened in any other case.

The histories of the following patients demonstrate some of the benefits which may be expected from the combined
creosote treatment, and I am pleased to be able to show five of the patients to the section this evening:

Case I.—F. H., aged twenty-three years, came to the hospital, July 23, 1894, complaining of difficult articulation owing to a stiff, painful sensation in the larynx and also considerable dysphagia. His family history was an unsatisfactory one, as his father died, aged forty-nine years, from pulmonary tuberculosis, and also three brothers, aged sixteen, twenty-eight, and thirty-one, respectively. The cause of their death was some throat affection the nature of which is uncertain, but from the histories was probably tuberculosis. His general condition was much impaired, and his appearance very anaemic. Afternoon temperature, 100° F.; pulse, 120. Considerable distress was experienced from severe night sweats and coughing. On examination, the upper parts of both lungs gave abundant evidence of tubercular infection in various stages of progress. The soft palate was very anaemic, and the laryngeal surface and tip of the epiglottic much thickened and rounded and very red in appearance. The coverings of the arytenoid cartilages were red, puffy, and of an edematous, club-shaped appearance. Examination of the sputa showed numerous tubercle bacilli.

Beechwood creosote was prescribed, and the larynx sprayed with an oily solution containing two drachms of creosote to the ounce. He visited the hospital three times a week, the internal dose of creosote being gradually increased and the spray continued. The laryngeal distress moderated considerably after the sixth application of creosote. Marked improvement was not apparent until the latter part of September, when the red and thickened appearance in the larynx diminished greatly and the dysphonia and dysphagia had about disappeared. The chest symptoms had not improved, and on the 21st of September the temperature was 102°² F., and on the 25th it had fallen to 101°₂. Thirty-six drops of creosote had been taken daily for a period of two weeks past. On his next visit, October 2d, his appearance and general condition had much improved. Temperature, 100°₂ F. This satisfactory improvement continued, and on October 19th he reported a gain in weight of four pounds in three weeks. Temperature was 99° F., and the cough, night sweats, and laryngeal symptoms had practically disappeared. The dose of creosote had reached sixty drops a day at this time, and the patient felt so well that he went to work.

He next visited the hospital November 2d, and reported a return of the night sweats and cough, accompanied by extreme prostration. He presented an ash appearance and every evidence of being very ill. The mucous membrane of the left arytenoid cartilage was swollen and red, and he complained of some pain on the left side of the larynx. Temperature, 100°₂ F. An injection of half a minu of pure creosote was made into the left arytenoid, which was followed by a burning sensation which lasted several hours. On the 7th of November the point of injection was still visible, but the infiltration present before the injection was made had about disappeared. The notes of November 12th show the temperature to have been 109° F. General condition, appearance, and appetite much improved. Voice good. No dysphonia or dysphagia, and, with the exception of a little redness over the arytenoids, the larynx presented a satisfactory appearance. A few weeks later his wife called to say that her husband was very weak, and that their circumstances did not permit his having sufficient nourishment. He was admitted to the Presbyterian Hospital under the care of Dr. A. H. Smith, and during his stay of seven weeks gained ten pounds in weight. He has now been home some five weeks, and has visited me at the hospital every week, but receives no treatment for his throat. His pulmonary symptoms and general condition are, however, far from satisfactory.

Case II.—Mr. E. N. S., aged twenty-nine years, first came under my care in 1887 complaining of lumbar aching, and he subsequently developed two small lumbar abscesses, one in 1889 and a second in 1891. After the latter there was a slight curvature of the spine, which Dr. Gilhey, who was called in consultation, said was due to tuberculous disease of the vertebrae. In the summer of 1894 Mr. S. had a troublesome cough and night sweats. An examination revealed numerous fine, moist rales, with dullness over the left pulmonary apex. Temperature, 101° F. The sputa contained quantities of tubercle bacilli and some elastic tissue. Under creosote and general tonics the chest symptoms greatly improved. He again consulted me on the 17th of December, 1894, in consequence of hoarseness and a feeling of soreness in the larynx, with considerable pain in swallowing. Temperature was 99-4° F.; pulse, 100. His appearance was one of general depression and lassitude; cough constant and irritating in character, and moderate night sweats.

The soft palate and pharynx were anaemic. Epiglottis red and somewhat enlarged; the arytenoids large and their mucous membrane red and puffy. The interarytenoid space presented several hypertrophies. Considerable eumes adhered to the surfaces of the arytenoids, epiglottis, and around the base of the tongue and in the pyriform sinuses. A microscopic examination of the meses showed plenty of tubercle bacilli. Creosote was prescribed for internal administration and the two-drachm-to-the-ounce solution of creosote sprayed into the larynx. A week later, after the third laryngeal application, the soreness and pain in swallowing were greatly diminished and the cough lessened. I did not see him again for two weeks when he returned complaining of slight pain in swallowing.

An examination of the larynx showed an almost entire subsidence of the redness, infiltrations, and hypertrophies already described, with no apparent cause for the pain in swallowing. The creosote solution was again applied, and a spray given for home use of one drachm of creosote to the ounce with ten grains of menthol added. He is still under this treatment and, with the exception of the vocal cords being slightly pink, the larynx presents a nearly normal appearance and he does not complain of any laryngeal symptoms.

Case III.—E. D., a woman, aged thirty-seven years, came to the hospital April 23, 1894, complaining of hoarseness. Several members of her family had died of phthisis, but little could be obtained of their history. About a month before her visit to the hospital she had noticed her voice becoming slightly hoarse. It gradually progressed until she spoke in a low whisper. There was considerable soreness in the larynx, which was more or less continuous and accompanied by slight dysphagia. Temperature, 99-4° F. Moderate dullness in left pulmonary apex and some fine moist crepitations. Soft palate anaemic, epiglottis and arytenoid cartilages normal in appearance. Mucous membrane of interarytenoid space red and somewhat tumefied. Ventricular bands red and much thickened and partially overlapping the vocal cords. The latter were much thickened and presented a grayish granular appearance. An examination of the sputa showed a few tabercule bacilli.

The administration and application of creosote was commenced at once and continued until May 25th, when she reported no laryngeal pains or soreness and voice quite clear. The infiltrations of the ventricular bands and vocal cords had diminished considerably. During the summer months she visited the hospital four times and gave every evidence of gradual improvement. On the 3d of November she complained of a return of the laryngeal pain and hoarseness.

A laryngoscopic examination showed the right band and cord much thickened and about in the same condition as when
I first saw her. Left cord and ventricular band much improved.

Submucous injections of the oily solution of creosote were commenced and have been continued once a week to the present time. One of the injections into the right cord produced considerable difficulty in respiration, which lasted several hours. At present she has no cough or laryngeal soreness. The hoarseness continues, but is much improved. The infiltration of the ventricular bands is much less, and the gray thickened appearance of the posterior half of the vocal cords has nearly disappeared, especially on the left. The anterior parts of the cords are still considerably tunnelled. The difference in condition of the anterior and posterior part of the cords is probably due to the difficulty experienced in making injections in the anterior part of the larynx.

Case IV.—M. J., aged thirty-two years, came under my care in September, 1894. He had had phthisis for two years, and the upper parts of both lungs were well infiltrated with tubercular deposit. Eight weeks prior to my visit he began to have pain in his throat and hoarseness. This condition gradually increased until the dysphonia and dysphagia became so great that he had taken to his bed, and had not swallowed anything for three days.

The epiglottis, arytenoids, ventricular bands, and, in fact, every part of the mucous lining of the larynx seemed to be infiltrated, and were in such an advanced stage of ulceration and necrosis that they were hardly recognizable.

Temperature, 103° F. Cough very troublesome and expectoration abundant. He was much emaciated, and his general condition so poor that any treatment seemed hopeless.

The larynx was cleared of secretions as much as possible and two injections of half a minim each of pure creosote made into the epiglottis. The oily solution was also thoroughly applied to the remaining portions of the larynx. The following day the necrosed portion of the epiglottis had separated, and the tension of the mucous membrane had considerably relaxed. This moderated the dysphagia and respiration became easier. Injectons and applications of creosote and oil were continued daily for a week. A great deal of sloughing tissue was thrown off during the week, and the surfaces were covered for the most part with healthy granulations.

The following week the solution containing one dram of creosote to the ounce was employed daily as a spray, and stimulated the granulating tissue so much that more soothing applications had to be substituted. Up to this time the dysphagia, although much better, was still considerable.

During the third week he swallowed with little pain, and was able to take plenty of nourishment. All the laryngeal symptoms had greatly abated, and an examination showed the remaining portion of the epiglottis to be much less thickened and the ulcerations healing. The general laryngeal thickening was greatly diminished, and the ulcerations over the arytenoids and ventricular bands were in various stages of cicatrization.

Some of the ulcers had entirely healed and gave the parts a wrinkled appearance.

This condition of comparative comfort continued for about two weeks, but the rapidly progressing pulmonary affection put a sudden end to the necessity for further laryngeal treatment.

Case V.—John B., aged twenty-seven, first visited the hospital December 3, 1894. He complained of having rapidly lost weight for three months past. About the 1st of November his throat began to be sore, and he had some slight dysphagia, which rapidly increased; it was almost impossible for him to swallow anything, owing to the severity of the pain. His articulation was also painful and his voice slightly hoarse. Cough constant and irriative in character, accompanied by a copious expectoration of thick, tenacious, and stringy mucus. Temperature, 102-1° F. Spurt loaded with tubercle bacilli. A pulmonary examination showed well-disseminated tubercular disease.

The tongue was red, phlogotic thick, and presented a cockscomb appearance, with small ulcerations covering its surface. The ventricular bands were thickened and the cords a light pink in color. The arytenoid cartilages were much enlarged and oedematous in appearance, and covered with small punctate ulcerations. A twenty-per-cent. solution of cocaine was applied to the larynx, and one drop of the two-drammes-to-the-ounce solution of creosote was injected into the margin of the epiglottis, also one drop into the right arytenoid. On the 5th a second injection was made into the epiglottis, and on the 7th one in the left arytenoid. On the latter date the epiglottis was found to be less thickened and paler in color. The dysphagia had slightly abated. After the last injection he was able to swallow all non-irritating liquids for an entire week with very slight pain; solids gave him a moderate amount of pain. The arytenoids had diminished in size, and many of the small ulcerations had disappeared. Cough and expectoration much less. This favorable condition of affairs continued for eight days, when the slight dysphagia reappeared. Temperature, 102° F. On the 21st of December the epiglottis, which had diminished in size and had had a very healthy appearance, began to look puffy, especially around the cushion; small grayish-looking spots appeared over its surface.

The following day, the upper part of the epiglottis seeming to be undergoing rapid necrosis, pure creosote was injected and partially relieved the dysphagia. From the 17th to the 24th of December the patient remained in the hospital, but his general condition became so poor that he was sent to his home in Brooklyn. Owing to the distance, he was unable to receive much further treatment. The upper two-thirds of the epiglottis separated and the stump granulated over. The rest of the larynx was covered with granulatative tissue in various stages of development. His cough was not very troublesome. The dysphagia was intermittent, sometimes causing great distress, and again he swallowed with comparative comfort. The loss of so much of the epiglottis allowed food to approach the glottis, and considerable care had to be exercised during eating or drinking. He died three weeks after his return home. The treatment while he was able to visit the hospital had been application of creosote in oily solution, and also its submucous injection and internal administration.

During the last two weeks cocaine was used at times to relieve the pain, and also several applications of iodiform, which afforded him great relief from pain for twenty-four hours. I regret to say that owing to the distance I only visited him once, and did not have an opportunity to continue the creosote treatment.

Case VI.—John B., aged twenty-seven years. Father died of phthisis. Has been hoarse off and on for over a year and has had several hemorrhages. During the past month he has had considerable dysphonia, dysphagia, and an incessant cough at night, with profuse expectorations. Temperature, 99-4° F.; pulse, 88. A few tubercle bacilli present in the spurt examined. Slight dullness with some fine crepituation and rales were present at the apex of the right lung. Epiglottis normal, arytenoid cartilages very much enlarged and oedematous. Intercartilaginous space filled with hypertrophied tissue covered with a granulatative process and a few spots of ulceration. Ventricular bands much thickened and completely overlapped the cords. The latter were seen after applying cocaine, and presented a granular appearance. One drop of fifty-per-cent. solution of lactic acid was injected into the anterior surface of the arytenoid.
slight laryngeal spasm followed the injection, and the patient reported considerable burning on the right side of the throat for two days. Laryngoscopic examination showed considerable edema around the point of injection. Three later injections of lactic acid were made, but, as there was little improvement, creosote was given internally, applied locally, and by submucous injection from the latter part of December, and had been continued until the present time. After the fourth application the cough diminished considerably and the patient spoke with less effort and swallowed with little pain. At times the creosote seemed to be too stimulating and had to be stopped for a few days. At present his condition is as follows: Cough almost absent. No expectoration. Dysphonia and dysphagia disappeared. No special discomfort in the larynx; the thickness of the ventricular bands and arytenoids cartilages has diminished so that the cords are partially visible. Ulcerations in the interarytenoid space have healed, but the hypertrophies have not diminished. Arytenoid cartilages still much thickened.

Case VII.—J. S., aged forty-three years, came to the hospital January 21, 1895, complaining of hoarseness, cough, laryngeal soreness, and slight dysphonia, all of about two months' duration. Temperature, 99.4° F. The upper part of left lung was found partially infiltrated with tubercular deposit, and numerous bacilli were found in the spuata by Dr. Reiling, pathologist of the hospital. Laryngoscopic examination showed the epiglottis to be normal. Both arytenoids thickened, especially the left. The ventricular bands were much infiltrated, red, and completely covered the vocal cords. Interarytenoid space contained several papillary masses, and was covered with grayish-looking mucous. When the latter was removed two or three small superficial ulcerations were apparent. The patient had been constantly under treatment since his first visit and has received creosote internally and by application and submucous injection. As you will see, he has made marked improvement under this treatment. The cough and laryngeal soreness are arrested, the voice is better, and the thickening of the ventricular bands and arytenoids has diminished, so that the cords are visible. The papillary condition of the interarytenoid space is much lessened and the ulcerations have healed.

Several other histories might be furnished from my case book, but those just related seem sufficient to draw attention to the combined creosote treatment.

A correct diagnosis is extremely important in considering the results of any treatment of laryngeal tuberculosis. When a patient with pulmonary tuberculosis develops laryngeal symptoms it is not always an easy matter to determine their nature. Some authorities have held that the initial infiltrations and local hypertrophies so frequently present are entirely of an inflammatory character; but the subsequent history of these cases if neglected, or if they remain untreated, is alone pretty conclusive evidence that the deposits are tubercular in character. Much more might be said on the subject of diagnosis, but it is not within the scope of this paper, and I have only mentioned the question as several of my patients presented infiltrations and hypertrophies which entirely disappeared under treatment without ulceration. Considerable difference of opinion may also arise on the decision as to when a case of tubercular laryngitis is cured. Much will depend on whether we claim that the result is a permanent one or simply that as a result of treatment there is no further evidence of laryngeal disease. The future of a larynx which has been the seat of tubercular deposit must depend greatly upon the progress of the pulmonary affection. If the latter is arrested, as is not unusual, no further laryngeal trouble may be experienced; but if the pulmonary disease remains stationary or progresses, there is always danger of reinfection, and it is not unusual for the laryngeal symptoms to fluctuate with the pulmonary condition. From a laryngologist's standpoint, I think it is usually conceded that we may call it a cure when all symptoms and appearances of laryngeal disease subside, although they may return at some subsequent period.

The history of Case I is interesting and instructive, as, in spite of the fact that the pulmonary condition was rapidly becoming worse, the laryngeal symptoms continuously improved. The present condition of his larynx is also very encouraging, as there are no symptoms or appearance of tubercular infiltrations, although the pulmonary symptoms are still active and his temperature is 102° F.

The other cases of laryngeal tuberculosis without ulceration did well, the cough, laryngeal soreness, and dysphagia being quickly relieved, and have not returned.

In Case II the red and infiltrated condition of the mucous membrane of the larynx has completely subsided, and the infiltrations in the other cases are in various stages of resolution.

One of the two cases seen after the ulcerative process had begun was gradually relieved of his laryngeal distress, and at the time of his death the seat of ulceration was covered with granulating tissue; and had not the pulmonary affection carried him off so rapidly, considerable further laryngeal improvement might fairly have been expected.

The second case with ulceration was a most distressing one from the first, but the creosote injections promptly relieved the severe dysphagia, and for a week the patient swallowed with comfort. Our inability to carry on the creosote treatment at his home in Brooklyn resulted in partial relapse of the laryngeal affection, but one can not help feeling that much more relief would have been obtained had constant treatment been possible.

The benefits we may expect from the combined uses of creosote may be summed up as follows:

1. It relieves dysphagia, dysphonia, laryngeal soreness, and the cough in the primary stages of laryngeal tuberculosis.

2. Infiltrations and hypertrophies disappear in some cases after persistent treatment; the earlier the treatment is commenced, the more rapid are the results.

3. If the pulmonary disease is very active, early treatment may arrest the laryngeal affection or postpone and limit subsequent ulcerations.

4. Single tubercular ulcers may be healed if not too deep or too great in circumference.

5. In the ulcerative stages the cough and expectoration and laryngeal distress are greatly diminished, the separation of sloughing tissue is hastened, granulations stimulated, and the odor of the secretions much diminished.

The similarity of these results and benefits compared with those obtained from creosote administered to cases of
pulmonary tuberculosis in the early stages is quite remarkable. I think it is not at all unlikely that further experience will prove that cases of laryngeal tuberculosis treated by the combined uses of creosote with suitable climatic and hygienic surroundings will give quite as good results as any other method of treatment. Creosote may be considered as occupying the same position to laryngeal tuberculosis as it already does to the pulmonary affection. Our present experience will not justify a positive statement regarding the curability of tubercular laryngitis in its advanced ulcerative stage. The opinion of the writer is that the pulmonary implication is so extensive and progressing so rapidly at this stage that an arrest and cure of the laryngeal disease by any measure must be very rare. Much, however, may be done for the dysphagia, dysphonia, cough, and excessive secretions, and it is chiefly for the relief of these symptoms that our efforts should be directed.

22 East Forty-second Street.

SOME REMARKS ON
EROSIONS AND ULCERS OF THE CORNEA
AND THEIR TREATMENT.*

BY CARL KOLLER, M.D.

It is not intended to give here a complete study of this interesting and important subject, but only to emphasize the general principles according to which corneal lesions have to be treated; besides, I shall mark out some points which personal experience has taught me to be of importance.

In dealing with corneal affections we must keep before our mind the peculiar anatomical and physiological attributes of the cornea: that it is a thin membrane without blood-vessels, but profusely furnished with nerve ramifications, covered on one side with epithelium continuous to that of a mucous membrane, on the other side with an endothelium; that it receives its nutrition from two different sources—in its upper layers by lymph currents fed from the conjunctival blood-vessels, and in the deeper strata from those tributary to the anterior ciliary blood-vessels. If we add that the high polish necessary for its function, protection from evaporation, is required and furnished by a constant irrigation with a salty fluid produced by the tear glands, the peculiar position of this structure is indicated. It is not necessary to dwell at length upon the great importance of maintaining the transparency and curvature of this precious little membrane in order to understand why every affection, even the smallest epithelial erosion, deserves our most earnest attention.

Every corneal erosion or ulcer, with the exceptions to be mentioned, demands the application of a well-fitting bandage; the popular eye patch or the dark eye glasses do not serve the purpose. The bandage ought to keep the lids closed without exerting pressure upon the eyeball. The closing of the lids prevents their rubbing upon the ulcer with every movement, thus irritating it and causing pain. Furthermore, closing of the lids keeps dust out from the ulcer which is sure to gather there, being protected in the recesses from the cleansing action of the flooding tears. Anybody who has witnessed the immediate relief experienced by a patient with corneal ulcer or erosion after proper application of the bandage will be convinced that this is the right kind of treatment. In progressive ulcer with threatening perforation of the cornea the bandage serves yet another purpose. If the cornea at the place of the ulcer is thinned down to the point where a violent movement—coughing, sneezing, pressing for stool by a sudden increase of pressure—will rupture it, the aqueous humor will flow out with a rush, the iris will prolapse to larger extent, and by the sudden emptying of the chamber the lens may become dislocated. If, on the contrary, the eye is supported by a semi-elastic bandage the perforation will occur in a more easy way: the aqueous humor, instead of rushing out, will flow off gently; the iris, instead of prolapsing, will only lay itself before the little hole, so that the ultimate result will be only a small adhesion instead of an extension with all its possible consequences. Of course, bed-rest will greatly contribute to this more favorable development.

The bandage should be changed at least once a day. Corneal ulcers and erosions are mostly accompanied by some conjunctival irritation with discharge, and to remove the latter, change of the bandage and cleansing of the eye is necessary. Where the discharge is more copious it precludes the use of the bandage altogether, since the latter would be conducive to locking up of the secretion, a condition most unfavorable for the healing of corneal ulcers. The use of a bandage, therefore, is precluded in corneal ulcers arising in gonorrheic ophthalmia, in trachoma, and even in the marginal ulcers occurring in chronic conjunctivitis of old cachectic people. It can be dispensed with in the lighter forms of ulcer from phlyctenular keratitis which are the rule in this country, whereas the extended, progressive, and deep, frequently perforating ulcers, very common among the poorer classes of large European cities, require different treatment.

Another measure of very great importance and fit for almost all cases of inflammatory trouble of the cornea is the use of hot poultices. The beneficial effect of such can not be too highly commended; it is well founded in theory and proved in practice. The corneal tissue, being devoid of blood-vessels, lacks the means of defense which other tissues possess against necrotizing influences in the increase of blood supply. A more liberal supply of lymph circulation will take the place that arterial congestion takes in the process of demarcation of necrosis in other tissues. On the other hand, in the healing stage of an ulcer it will promote the new forming of cicatricial tissue. To serve their purpose the poultices must not be made continuous; continual heat paralyzes the blood-vessels as continuous cold does. I generally recommend making them four times a day for an hour, and just as hot as patient can bear them, changing the compress about every minute or two. The compress must not be too thin to keep a sufficient amount of heat, and must cover a part of the forehead and cheek.

* Read before the Manhattan Medical and Surgical Society, January 26, 1895.
If properly made, the eye looks congested and the skin of the forehead and cheek shows a deep red. The patients always feel very much relieved by these hot applications, and, if anything, have to be cautioned not to overdo their use. In the intervals the eye is bandaged.

The use of atropine may be advisable, but it has its strict indications, and the indiscriminate instillation of atropine in every kind of corneal ulcer must be condemned. Generally atropine is useful where there is great irritation and much congestion in the case of erosions or ulcers of a central location on the cornea. Strictly speaking, atropine has in ocular therapeutics one chief indication—that is, to dilate the pupil when iritis is present or threatening. Now, it happens, or rather lies in the nature of things, that this latter indication exists only in lesions of a central location on the cornea. Every corneal lesion is followed by a congestion of the corresponding part of the ciliary system of blood-vessels; so we see in a more peripheral location of the lesion only the corresponding sector of the ciliary system congested; but in central lesions the whole ciliary system all around the cornea is filled and gives rise to the well-known pericorneal injection. The same system of blood-vessels—the anterior ciliary arteries—are the chief blood supply of the iris, hence we see in every case of ciliary congestion the iris congested also and the pupil tending to become narrow, which latter is a purely mechanical phenomenon. In case of an infected ulcer the congestion of the iris just described may turn into real iritis. The view is borne out by the fact that we hardly ever see iritis follow a corneal ulcer peripherally located. If the atropine is useless except where it fills an indication, it may be even harmful, making the ciliary blood-vessels anemic, thus lessening the lymph circulation and retarding the healing. This objection would not hold good against the general use of eserine, which a number of years ago was very popular in corneal lesions, and which would seem to serve similar ends as the hot applications—that is, to cause congestion of the ciliary system in the service of better nutrition. But the use of the eserine entails just the dangers which in many cases of corneal ulcer we have to combat—that is, complication with iritis, and, as far as I am aware, it is nowadays very sparingly used in corneal affections. There exists only one single indication for the use of eserine in corneal ulcers, and that is the case of a threatening perforation of an ulcer located at the corneal periphery. In such a case a contracted pupil may be very desirable to make the prolapse of the iris as small as possible if it does occur.

The use of cocaine as an anodyne in painful ulcers and erosions of the cornea is very common, but can not be justified either by practice or by theoretical considerations. The anesthesia produced by cocaine instillation lasts a very short time—hardly ten minutes—and the reappearance of sensation is accompanied by the reappearance of pain, so that the instillation would have to be almost continuous to be efficient. But this would be the slightest objection. It can be shown that the use of cocaine in corneal affections is positively harmful. Cocaine is a general protoplasmic poison, as more recent biological researches have proved; it first stimulates the protoplasma and afterward paralyzes it, prolonged and repeated action causing finally mortification. It is very easy to demonstrate that repeated instillation of cocaine into an eye causes a general slight haziness and dotted erosions of the corneal epithelium. I noticed these phenomena in my first experiments with cocaine, and was at first inclined to ascribe them to dryness and evaporation, due to arrested secretion of tears and diminished winking of the lids brought on by the local anaesthesia. But a series of experiments undertaken on rabbits established beyond doubt that although dryness plays some part in the haziness and exfoliation of the epithelium, it is chiefly due to necrosis of the epithelium brought on by the direct action of cocaine. Comparison with the physiological effect of other substances with local anaesthetic properties, like crotaphtholine, leads to the same conclusion. A direct proof for this view is furnished by the experiments of Albertson on the action of cocaine upon the vital functions and movements of ciliated epithelium, spermatozooids, and various protoplasmic cells of the lower forms of life. As in the treatment of corneal ulcers it is our task to fortify and enhance the vitality of the corneal tissue, we must abstain from the use of cocaine, which is liable to lower it.

As to our means of checking the progress of an infected corneal ulcer, besides the operation of paracentesis, in some cases the actual cautery is very much in favor, and justly, for since its introduction by Gayet many an eye has been saved that formerly was lost; with the use of cocaine the application of the cautery is entirely painless, and in fact its more extended use began with the introduction of cocaine as an anaesthetic. The actual cautery, however, has also its limitation, and it is by no means a panacea. One great objection is that to be efficient very much tissue must be destroyed—possibly more than when the demarca
tion would be natural. On the other hand, it is not a very rare occurrence that an ulcer, after cauternation has apparently stopped its progress, resumes its destructive stage again. The explanation for such is not difficult to find. The cautery, even if applied very liberally into apparently healthy tissue, will in many cases fall short of destroying every part of the infected area; besides, the source of infection is frequently in the conjunctival sac or in the lacrymal cyst, whence the most copious antiseptic irrigations can not eradicate it. The eschar produced by the cautery may be entirely sterile, but it forms a good soil for the germs of suppuration; and so we see in some cases the infection resume its course after a short stay and destroy what there is left of the cornea. The desideratum for progressive infected ulcer would be a remedy capable of diffusion into the corneal tissue and acting in an eclectic manner, destroying the germs of infection and sparing the tissue. To some degree tincture of iodine seems to act in this way. It is surprising how well the cornea stands the application of the strong tincture if properly executed, and how quickly sometimes progressive ulcers are brought to healing. One case has impressed itself very strongly on my mind. A man, sixty-nine years of age, unusually short of stature and rather decrepit, presented himself with one of those crescent-shaped ulcers on the inner margin of his right cornea which, before the introduction of the ac-
tual cautery, were considered incurable and which bear the very fitting name ulcer rodens, first given them by Mooren. If not stopped, such ulcers travel over the whole cornea, progressing with an undermined margin on the concave side of the crescent and cicatrizing on the convex side of it. They never lead to perforation, but never stop spontaneously until the whole cornea is converted into an opaque scar. To make them more dreaded still, they affect in most cases both eyes in succession. I applied the galvano-cautery, using besides other suitable measures; however, that stopped the ulcer only for a few days. The margin became infiltrated again, and the use of the cautery was repeated. Within four weeks I had resort to it four times, during which time the ulcer became larger, while the remaining part of healthy corneal tissue was reduced to a very small spot, almost surrounded entirely by the ulcer. Now a similar infiltration showed itself at the inside of the left cornea. Unwilling to bear the responsibility any longer alone, I proposed a consultation with another oculist. He also advised the use of the cautery. So I cauterized both eyes, being very little hopeful of the result, my patient being almost desperate. After a few days the infiltration of the margin showed itself again in both eyes. I decided not to repeat the use of the cautery and tried tincture of iodine, which I had used before in minor cases. I applied it once every day; within a week the ulcers were rapidly recovering and after two more weeks were completely healed. The patient has very good vision in both eyes, even in the first attacked, the healthy remainder of the upper strata of the cornea having been drawn back into its former position by cicatrization like a shrunk flap of the skin, gaining considerably in size.

### A CASE OF AGORAPHOBIA.

**By Neville Taylor, M. A. Cantab.**

G. A., aged twenty-six years, consulted me about attacks of what he termed "nervousness." On inquiring their nature, he described them as "horrible feelings of fear with palpitation of the heart," occurring when about to cross a street or square, or when left alone in any large open space. When the first attack occurred he was in Austria, and about to set out for a walk over an extensive plain. This was about five years ago. He attributes their onset to the loss of a lifelong friend, a companion who had accompanied him everywhere.

He has always had good health, but has lately suffered from constipation and indigestion, and from the age of puberty he has been subject to recurrent attacks of acne. He was treated in Vienna for a "soft sore" three years ago; he has never had any secondary symptoms. He is very temperate, eats and sleeps well, and is a heavy consumer of cigarettes, smoking an ounce of Turkish tobacco a day. His father, a Russian, mother, a Pole, and two sisters are alive and well; no brothers. There is no insanity, hysteria, or any other neuroses in the family history.

The patient is a very intelligent and well-educated man, living the sedentary life of a clerk, a good linguist, and commanding a good salary. The heart and other viscera are healthy, the reflexes normal, and there is no evidence of any organic disease.

The urine has a specific gravity of 1.020; no albumin, sugar, or oxalates, and amount normal.

The above-described case evidently belongs to that class of mental deviations described under the head of "imperative ideas," the impulsions intellectuels of the French alienists.

Ribot classes "fixed ideas" into three categories:

1. **Simple fixed ideas** of a purely intellectual kind, which usually are confined to the consciousness, or which have no outward expression save in insignificant acts.

2. Fixed ideas accompanied by emotions, such as terror, anxiety (agoraphobia, folie de doute, etc.).

3. Fixed ideas of the impulsive kind, irresistible tendencies, which express themselves in violent or criminal acts, as robbery, homicide, or suicide.

Verga describes cases of "chustrophobia," "acrophobia," and "astrophobia."

Westphal, who described this class in 1872, gives a typical case: "A traveler of sound constitution, perfectly sound mind, and presenting no disorder of the motor faculty, is suddenly seized with a feeling of alarm at the sight of an open space, as a public square of some little size. If he must cross one of the great squares of Berlin, he fancies the distance to be several miles and despairs of ever reaching the other side. This feeling grows less or disappears if he goes round the square, following the line of houses, or if he has some person with him, or if he supports himself on a walking cane."

Carpenter quotes an instance of what he calls "paralysis of the will," which seems to belong to the above category. If, "when walking the street, this individual came to a gap in the line of houses, his will became suddenly inoperative and he could not proceed. An unbuilt-on space was sure to stop him. Crossing the street was very difficult, and on going in and out of a door he was always arrested for some minutes."

The French term for this condition, le peur des espaces, is a very illustrative one.

Imperative ideas are more commonly met with in females during or after menstruation or in pregnancy, in the young, in the weak-minded, and in the convalescent after fevers.

Krafft-Ebing considers that the patient is seized with the idea that he can not cross the street or square, and that he then works himself into an extraordinarily nervous and fearful condition. He considers this to be an expression of an irritable weakness of the nervous centers, founded on a neurasthenic basis, constitutional or acquired. He considers prognosis unfavorable as regards the chance of complete recovery from this mental condition, especially if the patient becomes more and more unsociable and exclusive. Some have long intermissions, some end in mental torpor, while a few, based on acquired neurasthenia, may recover.

In my case the patient was haunted by the fear of insanity, suggested to him by some not very discreet practitioner he had consulted previously. While Charteris remarks that in some instances there is a history of hereditary insanity or epilepsy, Krafft-Ebing says that these cases
never or seldom find their way into asylums. There is a very wide margin between the person who is conscious of the insistence and at the same time of the absurdity of an idea and the person who is conscious of the idea but not of the absurdity of it, and whose conduct is therefore influenced by it.

Westphal regards these attacks as allied to "epileptic vertigo."

According to Cordes, the primary cause is "a paralytic exhaustion of the motor nervous system, of that portion of the brain which governs not only locomotion but muscular sensibility also." My patient was reassured about his fear of insanity, and was advised to take as much exercise as he could, but not to tire himself physically or mentally; to fight against the ideas at every opportunity, to attend to the bowels, and to moderate the use of tobacco. A sea voyage was also suggested.

He was seen again after a short time, but there is no particular change in his condition. However, he says that he feels more confident of overcoming the attacks altogether—a confidence in which I regret I do not share.

A CONTRIBUTION TO THE STUDY OF WATER-BORNE CHOLERA.*

By George Homany, M.D.,
Health Commissioner, St. Louis.

In the burying ground of the St. Louis Quarantine Hospital stands a plain monument, erected, as the inscription upon it reads, in memory of one hundred and seventy-five non-commissioned officers and soldiers of the Fifty-sixth United States Colored Infantry who died of cholera in 1866.

It chanced that this monument and its meager inscription were brought to my notice at a time when I was somewhat occupied looking into the history of epidemic cholera, and the mortality recorded seemed so excessive that I was led to gather what further information I could in regard to it.

To this end I applied to the Surgeon General, United States Army, who in reply sent a copy of a War Department circular issued from the office of the Surgeon General, dated May 4, 1867, which was stated to contain all the data known respecting the cholera epidemic among the officers and soldiers of the regiment named in 1866.

This document contains no account of this outbreak by any medical officer who had personal knowledge concerning it, but includes a report by the commanding officer, dated August 18, 1866, from which, together with information obtained direct from the War Department and other sources, the following facts were taken:

Early in August, 1866, the regiment in question was on duty in Arkansas, five companies being stationed at Duvall's Bluff, and the remainder of the command, with regimental headquarters, was at Helena.

Being ordered to proceed to Omaha via St. Louis, the command, seven hundred and eight strong, assembled at Helena, and the five companies that had been at Duvall's Bluff embarked on board the steamer Continental on the evening of August 9th. The remainder followed on the Platte Valley the next morning.

The colonel states that the command had been unusually healthy during the summer, and the surgeon confirms this, saying that the regiment was in the best of health at the time of embarking.

No medical officer accompanied the command on this fateful journey, which has but one known parallel in American military-medical history, and perhaps few anywhere else.

Within a few hours after the boats swung out into the current of the Mississippi River mischief began, and by the time the Continental reached Cairo she had on board thirteen corpses and between fifty and sixty cases of cholera, all belonging to this regiment. More than fifty men of this command died on this boat before St. Louis was reached, the second boat not suffering so severely, but hardly a soldier in the entire regiment escaped an attack of the disease.

About a week after these troops left Helena the commander reported the deaths to that time among his men as one hundred and thirty-nine, but the end was not reached until the number recorded on the monument had perished, if, indeed, that number is correct, as it appears from the War Department records and information from other trustworthy sources, that the mortality in this body of men from this one cause was nearer one hundred and ninety than one hundred and seventy-five—a loss of more than one in every four in the command.

Of course, as thinking beings the question occurs to us, What caused this sudden and appalling outburst? And having duly considered the clouds and the moon and the malign influence of the stars without satisfactory result, we are compelled to look under our noses, so to speak, and study the immediate facts and circumstances connected with it.

At the time the regiment left Helena, sound and well, for this place, people were dying of cholera here at the rate of more than a hundred per day, the reported deaths from that disease in St. Louis for the week ending August 17th being seven hundred and fifty-four, and a very large proportion of the total deaths from this cause occurred in the territory between the river and Seventeenth Street and Cass and Chouteau Avenues. This territory was pretty well drained by sewers—the total length of public and district sewers here in 1866 being about fifty miles—and during the course of the epidemic the sewage thus poured into the river was heavily charged with the specific cholera organism.

The average stage of water in the river during that August was about twelve feet, and in view of all the facts elicited in regard to this occurrence, and of what is so well known now concerning water-borne cholera, there can remain no reasonable doubt that this body of men was poisoned by St. Louis sewage borne in the current of the river as far south as Helena, for the soldiers began to sicken.

* Read before the Association of Alumni of St. Louis Medical College, April, 1894.
and die within twelve hours after embarking, and no other source of water supply was accessible to them except the river.

As already stated, this incident, in the extent of fatalities attending it, stands with but one known equal in American history, according to data furnished by the Surgeon General, and a very imperfect examination of reports of foreign occurrences of like nature shows but one instance where cholera mortality in a similar organization was exceeded, and this will be noted presently.

In an address on Water borne Cholera, by the editor of the British Medical Journal, delivered in July, 1893, before the American Medical Association, evidence was heaped on evidence showing the direct, positive agency of polluted streams, used as sources of human water supply, in the causation and spread of Asiatic cholera.

In the abstract of sanitary and consular reports issued by the Marine Hospital Service for the week ending November 4, 1892, there is a report from the American Consul at Odessa, dated at Tashkent, Turkestan, September 9th, same year, which contains most signal proof of this contention, and with your permission I will cite a small portion of it. He says:

"At Samarcand three regiments of infantry were encamped side by side on a level plain close beside a stream of water. The colonel of one of the regiments took the most extraordinary pains to prevent his men from being attacked with the cholera, and he succeeded. In the first place, he caused every article in camp to be thoroughly cleansed with hot water and then disinfected. He compelled his men to bathe every day in hot water that had been boiled, and a guard was constantly maintained, whose duty it was to keep the soldiers from drinking the river water and to carry out the colonel's instructions. The result was that not a single case of cholera occurred in the regiment, while the other two regiments which were camped alongside lost over a hundred men from cholera. In these regiments the ordinary precautions were taken, but no such measures were adopted as I have mentioned above."

Again he says:

"At Ashabad the cholera had almost disappeared early in August, and the event was celebrated with much rejoicing on the anniversary of the Emperor's name-day, which occurs in that month. The Governor-General gave a dinner, to which he invited a numerous company, and the various regiments were granted extra rations that they might rejoice on the occasion. The day, which began so auspiciously amid general rejoicing, was destined to have an ending which has no parallel in history. Of the numerous guests who attended that dinner, one half died within twenty-four hours. A military band of about fifty men who played during that fatal dinner lost forty of their number with cholera, and only ten of the men reached camp that night. One regiment lost half its men and nine officers are the sun rose the following morning, and within forty-eight hours thirteen hundred people died with cholera. The cause of this outbreak was clearly traced to a small stream of water which supplied the town. Four days previous the authorities were informed that cholera had broken out at a small Turkoman village situated on the banks of this stream about four miles from Ashabad. The inhabitants of this village were ordered to move their kritikas (tents) several miles back on the hills, which they did. On the day previous to the reappearance of the cholera at Ashabad a very heavy rainstorm occurred which washed the banks of the river and swept refuse and other matter from the abandoned village into the stream, and this matter was carried by the water into the city and distributed to all parts of the town by the numerous open canals through which the inhabitants were supplied with water. It was this contaminated water which caused the reappearance of the epidemic and the frightful mortality which followed. The population of Ashabad was not more than thirteen thousand, of which ten per cent. died within forty-eight hours."

Returning now to the Mississippi River, what evidence other than that of an inferential character can be brought forward in support of its impudence as a death-dealing stream in 1866!

It happens that confirmation strong and proof convincing is afforded by the War Department document already cited in the account it contains of cholera among the troops at New Orleans the same year, the facts in brief being as follows:

On July 30th, on account of riotous disturbances in that city, the Eighty-first United States Colored Infantry was stationed at the foot of Canal Street and remained there ten days, during a part of which time the men drank water from the river, and many cases of cholera occurred until pure water was supplied, which had a most marked beneficial result, according to the surgeon's report.

The supply of distilled and rain water for the use of the One Hundred and Sixteenth United States Colored Infantry was scant for a day or two and some of the men used river water. Soon two cases of cholera appeared. Pure water was supplied and there were no more cases in the regiment.

Again, the Ninth United States Colored Cavalry and Thirty-ninth United States Infantry were supplied, but not sufficiently, with distilled water until the eisterns at their camp could be repaired and filled. At first the distilled water, sent hot in casks, could not become cool before it was needed. The men preferred to drink the river water because it was cold, and did so against orders and repeated warning; accepting the risk of disease rather than wait for the water to become cool and aerated. Case after case of cholera followed. Critical inspection failed to develop any other probable cause except the use of river water, and recommendation was made to move the regiments away from the river far enough to prevent the men obtaining it. To avoid moving, the cavalry put on a strong guard to keep the men from the river, and eistern water was supplied them. Cholera from that time ceased in these regiments.

In view of the foregoing facts, much interest attaches to the question as to the origin of the cholera virulence of the river water at New Orleans, for at that time there was no sewage flow from that city into the river in front of it, nor was there any sewerage system worthy the name in any town or city above it nearer than St. Louis.

No cholera was known to exist at Helena while the Fifty-sixth Regiment was there, although before its departure the surgeon informs me that this disease was reported as being present in St. Louis and New Orleans.

Up to the time of embarking, the command in question
drew its water supply from wells and springs which were kept free from surface contamination.

Upon a full consideration of the facts and circumstances connected with this epidemic there seems to be no escape from the conclusion that the Mississippi River was poisoned from here to the Gulf of Mexico by cholera-infected sewage in the summer and fall of 1866; that the source of that sewage was St. Louis; that a flow of over one thousand miles in open channel failed to free those waters of perilous risk to human health and life, and that this fact should lay forever in its grave the worn-out notion that water can purify itself of such living elements by merely flowing any distance whatsoever—a notion or superstition held by many who should know better, and dating from a time when no living thing much less in size than a tadpole was recognized as existing in water.

In the extracts from correspondence accompanying this paper mention is made of the eating of raw sugar by the soldiers while en route to St. Louis as being a possible or actual cause of the frightful mortality experienced, especially by the detachment on board the Continental.

That sugar alone could produce such a result is impossible, else cholera epidemics would occur daily; but recent investigations serve to throw much light on the rôle sugar may have played in this instance. The responsibility of the common house fly as the active medium in the infection of food substances, and causation of otherwise mysterious outbreaks of cholera, seems well established; and the infection at New Orleans of the sugar carried by the Continental, or while en route, may be explained in this way, and sufficiently shows the relation of cause and sequence when the partiality of flies for alvine dejecta and saccharine substances is borne in mind.

I beg to add, as tending to throw additional light on the subject-matter of this paper, some extracts from the correspondence of those who were, more or less, actors in this tragic occurrence. They are as follows:

From a letter from Daniel A. LaForce, M. D., of Ottumwa, Iowa, late Surgeon Fifty-sixth United States Colored Infantry, dated January 26, 1894:

"I was in charge of the United States General Hospital at Helena, Ark., in July, 1866, when the Fifty-sixth United States Colored Infantry received orders to go to Fort Leavenworth, Kansas. I had orders to turn over the hospital supplies and join the regiment at Fort Leavenworth.

"There had been very little sickness in the regiment during the spring and summer. The regiment was camped near the hospital, and the sick reported to me at the general hospital for treatment. The assistant surgeon was on duty at Duvall's Bluff with two companies of the same regiment.

"There was no medical officer to accompany the regiment, as it was necessary for me to stay long enough to turn over the hospital supplies. The regiment was in good health at the time of leaving. I followed in about three days and found it in quarantine near St. Louis. Surgeon Swift, of the regular army, was in charge of the camp, and I relieved him. There were two young city physicians who volunteered to assist in caring for the cholera patients. They were noble, whole-souled, and untiring in their efforts to aid us in the care and treatment of the cholera patients. Their names were Outten and Quaries.

"As stated, the regiment was in the best of health when they embarked on the Continental or Platet River. We knew of no cholera on the boats until it broke out among the troops about twelve hours after leaving Helena, and by the time they reached Memphis there were about forty cases reported. There was no medical officer with the regiment except a hospital steward, so Colonel Bentzoni, commanding, employed a physician to accompany them to St. Louis.

"It was currently reported and believed that the eating of the raw sugar by the troops was the cause of the epidemic. Four or five hundred of the regiment had the cholera and a hundred and seventy-five died at quarantine, to whom a monument was erected by the surviving members. The scourge abated by the latter part of August, and the regiment was mustered out of service September 15, 1866."

From same, under date of February 2, 1894:

"In answer to your inquiry as to the source of water used by the Fifty-sixth Regiment, United States Colored Infantry, at Helena and Duvall's Bluff, would say that I did not accompany the detachment to Duvall's Bluff, consequently am not able to state the source of water supply at that place.

"At Helena the water was from springs and wells. They were kept clean and free from surface water. It was my opinion that the water was pure.

"The regiment was encamped mostly in log barracks erected by the soldiers on the east side of a sloping hill with sandy loam. They used the water from the same source for about two years. Quite a good many of the soldiers died the first year of malarial fever and small-pox. In the early part of the cholera epidemic nearly every one that was attacked died in a few hours. Later on the disease became less fatal. I remember that nearly every soldier in the ranks suffered with an attack more or less virulent. A hard-fought battle would have been a picnic to going through the ordeal of the scourge. I think few caused many of the cases to be fatal among the negroes. I saw some cases die in two hours from the appearance of the first symptoms. They seemed to be in a stage of collapse almost from the start. Several officers had the cholera, but only one died, and that was Lieutenant Joe Brooks. He had so far recovered as to be able to be sent home to his father, Rev. Joe Brooks, of St. Louis.

"Cholera had been reported at New Orleans and some other points on the lower Mississippi and at St. Louis shortly before the regiment vacated Helena; but up to that time there had been no case reported at Helena."

From W. B. Outten, M. D., St. Louis, under date of January 26, 1894:

"In August, 1866, Colonel Labadie, then Department Surveyor of the United States Army at this point, solicited Dr. B. S. Anderson and myself to attend to a negro regiment which was then in transit, and among its numbers cholera had already appeared. The St. Louis Quarantine Station on the Iron Mountain Road, at its present position, protected the Mississippi River and prevented any arrivals who were foolish enough to come up by the river at that time, and there were not any who did come except in this instance a portion of the United States Army returning from the South.

"Accordingly, I signed a contract and went immediately down to quarantine, arriving there in the evening. The negroes had died so rapidly that they were not encoffined, but enshrouded in their blankets and buried at the old quarantine graveyard. I continued my work there for two days and two nights without any assistance; neither Dr. LaForce nor his as-
HOMAN: WATER-BORNE CHOLERA.

On the third day of my arrival I managed to induce Dr. R. A. Quarles, who is now a resident of this city, to come down and help me. He and I remained with the regiment until the cholera ceased. If I remember correctly, out of a regiment of some seven hundred, in the neighborhood of some six hundred or more were affected with the disease, and in the neighborhood of two hundred died from this cause.

"There is only one element of success in connection with this trouble, and that is in the direction of prevention, and which was indulged in in the epidemic at quarantine. We had sick call night and morning, and, instead of giving medicine to the collapsed men, we attended to the furred and coated tongue and inflamed diarrhoea—that is, kept the well from being sick and thus robbed cholera of its material, and at the end of ten days no new case of cholera presented itself."

From Major Charles Bentzoni, United States Army, late Colonel Commanding Fifty-sixth United States Colored Infantry, dated February 27, 1894:

"The troops on the Continental had been stationed at Duvall's Bluff on the White River. I think they came down the river on another boat and were transferred to the Continental. Both the Continental and the Platte Valley came from New Orleans, where cholera had been epidemic for some time. There were rumors that cases had occurred on one or both the vessels, but I had neither time nor opportunity to make inquiry. The troops on the Platte Valley, on which boat I was, had been stationed at Helena. Aside from malarial affections, there was no sickness in the command at the time of embarkation. It is true that officers at the time laid much stress on the fact that men on the Continental had been eating raw sugar in great quantities; but there was no such cause on the Platte Valley. As to the probability of being infected by the water, I call your attention to the fact that the Continental, after only a ten hours run with the troops aboard, left the first case dying on the wharf at Memphis; and on the Platte Valley I buried the first case about fifty miles above Memphis. This is a very great distance from the supposed source of infection. In short, I believe both boats were infected at New Orleans.

"I engaged a Dr. Perkins at Cairo, and he had charge of the sick on the Platte Valley until we reached St. Louis."

From James Sykes, M.D., of Beverly, Ill., late Assistant Surgeon, Fifty-sixth United States Colored Infantry, dated April 2, 1894:

"About the 1st of April, 1866, the second battalion of the regiment, consisting of Companies B, D, E, G, and K, were ordered to Duvall's Bluff, on the White River, in Arkansas, with myself as medical officer in charge. The command enjoyed excellent health till we were ordered to St. Louis, Mo., about the 1st of August, when the battalion rejoined the regimental headquarters at Helena, Ark. We had a few sick at that time—I think about eight or ten—but there was nothing peculiar about their sickness, I being left with them. Two weeks later they had all recovered sufficiently to travel, and I went by boat to Helena with them. A few days before we left Duvall's Bluff—say, about the 8th or 10th of August—there occurred two or three cases among the citizens that were strongly suspected to be cholera, and, from my subsequent experience with cholera, I am now satisfied they were genuine Asiatic cholera. I think these cases were still sick when we left, as I have no recollection how they ended. At that time cholera was prevailing along the river towns and on the boats. The troops at Duvall's Bluff used river water, which at that time was very clear, but hot.

On our arrival at Helena we found the regiment gone to St. Louis, leaving on two boats. There had been a few cases of cholera at Helena when we arrived, and I think some of them occurred before the troops left. So I think it entirely probable that they had the microbes with them when they went on board. From the officers with the troops I learned at the time that most of the cases occurred on one boat, I think Surgeon Duvall's was with one boat, but I forget which one. They informed me that several cases occurred before the most infected boat reached Cairo, where the colonel took on two citizen doctors.

"I was informed at the time that the most infected boat had a quantity of raw sugar going to the refineries, and that the soldiers, being on the boiler deck, burst open several hogsheads of it, and ate only colored men. My own theory is that the soldiers either took the cholera, microbes from Helena or else they were already on the boat, and then, gorging themselves with raw sugar, allowed the pestilence to get in its deadly work. The fact that but very few officers took the disease at all, and they in a light form, would seem to indicate that it was something in the diet, rather than the water, as all used river water alike. But one officer died (Lieutenant Brooks), and he from a relapse occurring after he had recovered so far as to take a leave of absence to visit his family living in St. Louis. After the troops arrived at St. Louis they were removed to quarantine, and the cholera became general among all the companies. The above is from memory, and while I doubtless have forgotten some facts, the narrative is substantially correct."

From George M. Sternberg, Surgeon General, United States Army, under date of March 7, 1894:

"In connection with your reference to mortality from cholera in your letter of January 26, 1894, I desire to invite your attention to an extract from a report of Major-General Macomb, given on page 81 of Forry's Medical Statistics, United States Army, Washington, 1840, as follows:

"'Of the six companies of artillery which left Fort Monroe, five companies arrived at Chicago in the short space of eighteen days. . . . The loss by cholera in that detachment alone was equal to one out of every three men.'"

Note.—Since the foregoing was written the subjoined statement, under date January 17, 1895, has been received from Captain J. M. Thomas, who commanded the detachment on board the Continental, and which presents such a vivid picture of pestilential ravages—which, it is hoped, could never again occur in this country—that it is given nearly in full. The account is as follows:

"Replying to your request for information in detail concerning the cholera epidemic of 1866, and especially as it affected the Fifty-sixth United States Colored Infantry, will say: 1. The health of the detachment at Duvall's Bluff during our stay there was very good. 2. We left there about the last of July to rejoin our regiment at Helena, Ark.; the name of the boat carrying us I do not now remember, but I considered its sanitary condition good. 3. When we embarked for Omaha, Neb., on the steamer Continental, August 10th, no cholera was known to exist along the Mississippi River at any point either above or below Helena. 4. The health of the passengers on the Continental was good and the sanitary condition excellent. 5. She was from New Orleans en route to St. Louis, and carried about thirty passengers.

"I will state that, on the 9th day of August, while at Helena, one of my men was taken violently ill and in a few hours died. The doctor certified his death to be caused by 'congestive chill,'
but I must say the symptoms were identical with many others who afterward died and were called cholera deaths.

"We left Helena on the 10th of August with orders to report to the commanding officer at Omaha, Neb. At that time the health of the command was good. We had not gone far when an officer of one of the companies reported to me that one of his men was very sick and, he feared, was going to die. I directed that he should be sent to the military hospital at Memphis, Tenn., when we reached that point, which was done. I afterward learned that the soldier died. Next day, the 11th, many more were taken sick, and we began to realize that we had cholera with us in all its violence. The crew and passengers became pale and striken, and for a time it seemed as if a Jeżeli terror had taken possession of all on board; men prayed who never prayed before, pleading with their Maker to stay the pestilence. On our arrival at Cairo, Ill., three of our men were dead, and fully one hundred very sick. We called on the Mayor of that city to bury them, but he refused, saying, 'You have cholera on board your boat, and I want you to leave this city at once,' and slammed the door shut. Having no medicines or doctor on board, I tried to hire a physician to go with us to St. Louis, but none could be induced to take their chances on a floating pesthouse, as our vessel was at that time. We went to a drug store and purchased forty dollars' worth of cholera mixture, and returned to the boat and found that four others had died while we were away.

"After leaving Cairo I directed Captain O. R. Sensibaugh, my next officer, to land at some convenient point as soon as possible and bury the dead, retiring to my state room for much-needed rest, not having slept one moment since leaving Helena.

"About eight o'clock in the morning Captain Sensibaugh came to me and informed me that my orders had been obeyed, and that he had buried twenty-one men and one woman (a soldier's wife).

"About 5 p.m. we made a landing on a small island thickly timbered and buried twenty-one men and one woman, also a soldier's wife. On the morning of the 13th, as we neared Jefferson Barracks, we landed on the Missouri side for the purpose of burying ten men who had died during the night. One of the men, who assisted in carrying off the first body, on returning to the boat was taken violently sick, falling full length as if struck with a hand-spike, and was dead before the others were buried, and was carried off and laid beside them, increasing the number to eleven, making a total of fifty-three men belonging to our command and two women, soldiers' wives, buried between Cairo and St. Louis, all in the space of thirty hours.

"Arriving at Jefferson Barracks, I went to the telegraph office for a reply to my dispatch previously sent to General Sherman, but found no answer; therefore we were compelled to proceed to St. Louis. Upon our arrival at the wharf I directed Captain Washington to anchor in midstream while I reported to General Sherman for orders. I immediately required to head-quarters, only to learn that he was in Nebraska, and my message had been forwarded, but no reply had been received, and no one at the general's headquarters would assume the responsibility of sending us to quarantine, as requested. We were thus compelled to wait until about 4 p.m. before the order came, as follows:

"'If Captain Thomas, commanding detachment Fifth-sixth United States Colored Infantry, has cholera on board, send them to quarantine.'

"Colonel Swift, United States Medical Department, had anticipated the order and was already at quarantine, having proceeded by rail, and had hospital tents up and ready to receive our sick as soon as we should land. He was accompanied by Dr. W. B. Outten (now chief surgeon, Missouri Pacific Railroad), and Dr. Quares, of your city. After leaving General Sherman's headquarters, accompanied by Mayor J. S. Thomas and Captain (afterward Mayor) Joseph Brown, we were conveyed out to the steamer Continental with its awful cargo of human freight. When we landed at quarantine twenty-eight dead soldiers were carried off the boat, besides more than two hundred sick ones.

"Colonel B. L. E. Bonneville, United States Army, commanding at Jefferson Barracks, kindly sent a detail each day to bury our dead, for we had not men enough to attend to it. Our total loss was one hundred and eighty-four enlisted men and one officer—First Lieutenant Joseph Brooks, Jr.

"Colonel Bentzon, with the remainder of the regiment, came in on the next boat and camped near us, and a day or two later we were joined by Major Wells and Dr. Sykes, our assistant surgeon, both of whom had been absent on leave.

"It was said our sickness was caused by eating unrefined sugar, with which our boat was loaded; but I do not believe our ills could be laid to that charge, for thousands died in St. Louis and other places all over this country who never tasted raw sugar, and, besides, a very few of the men had eaten of the sugar at all.

"The commissioned officers suffered very little inconvenience from the effects of the epidemic; most of us lived, as near as possible, the same as before. I had it quite severely, but attributed it to my having lost so much rest while attending to the needs of others, my sickness occurring several days after reaching quarantine.

"I had then served in the volunteer service of the United States for more than five years, had endured the usual hardships of camp life, and am free to say that I would gladly have served it all over again rather than pass through those scenes again, and witness the horrors of another cholera epidemic such as I did in the year of our Lord 1856.'

THE THERAPEUTICAL EFFECTS OF BETA-NAPHTHOL BISMUTH.

By HUGO ENGEL, A.M., M.D.,
FELLOWSHIP OF THE AMERICAN ACADEMY OF MEDICINE;
LATE PROFESSOR OF NEUROLOGICAL DISORDERS AND CLINICAL MEDICINE IN PHILADELPHIA, ETC.

Shall each decade of the nineteenth century be given a name to represent the progress made and the activity displayed during it in the various branches of medicine, we might bestow upon the period of the last ten years the appellation of the epoch of the discovery of new remedies. It, indeed, is not easy to keep step with the rapid march of advancement in therapeutics. And it is not only the great number of new drugs—through so great as to cause our admiration of the wonderful fertility of the human brain in the invention alone of names for them—but it is also their valuable character, the definite results following their employment, that has made this decade so remarkable. That some chaff is mixed up with the wheat scarcely deserves mention; wherever truth and real worth achieve victories, humbug is bound to claim its portion; but when it appropriates to itself the lion's share, it can do so only by proving the correctness of the adage: *Mundus vult decipi, ergo decipiatur.* Fortunately, since a higher standard of medical education has extended the grasp of the intellect, that proverb to-day finds but little application to physicians, and the harvest of proprietary remedies, whose sole vir-
The internal application of the phenols has thus far been but a very limited one. In their free state they are exceedingly poisonous, their caustic action is deleterious to the mucous membranes of the alimentary canal, and they possess, besides, a very disagreeable odor and are repugnant to the taste. In their combination with bismuth they seem mutually to neutralize these obnoxious properties, and when thus introduced into the human system they again form the various phenols with all their therapeutic effects, the oxide of bismuth also being liberated and fixing the toxic albumins in the intestines.

From the reports of experiments made in Professor Nencki’s Laboratory at the St. Petersburg Imperial Institute for Experimental Medicine,* we learn that beta-naphthol bismuth, when introduced into the stomach, is decomposed into naphthol and bismuth to some extent; some passes on into the intestines, where the conditions are also favorable to its complete decomposition from the acid reaction of its contents and the presence of the pancreatic juice. Naphthol is but partially eliminated with the urine; the residue passes through the whole alimentary canal, and is finally excreted by the feces. Bismuth, on the other hand, is totally excreted with the feces as sulphide (in man; in the dog not, because of the relatively much greater amount of muriatic acid in that quadruped, causing the formation of some soluble chloride, but most of it undergoing the same changes as in man). In no single case were any toxic symptoms observed, though administered in daily doses of seventy-five grains (one hundred and fifty grains to dogs).

Another observation showed that all the combinations of the phenols with bismuth undoubtedly arrested the development of bacteria—an important fact which, though explained by the separation occurring in the intestinal tract, yet by itself explains the remarkable effect of these remedies in certain bowel complaints.

Professor Hueppe † also found beta-naphthol bismuth a most powerful intestinal antiseptic, and recommends it as a specific in Asiatic cholera. He treated a number of cases with it in one of the Hamburg hospitals. Von Nencki ‡ noticed that the drug was well borne by patients even when continued a long while. Other Russian physicians § administered it in Baku in daily doses of fifteen to thirty grains in choleric diarrhoea and allied diseases, and, while recovery occurred in almost all cases, injurious effects were not noticed in any.

Wilcox * read last December a paper on bismuth in general, in which he speaks highly of the combinations in question, and finds the beta-naphthol bismuth especially indicated in all fermentative bowel complaints.

By Jasenski † it has been used with success in chronic intestinal catarrh and in cancer of the stomach. The cramps and the vomiting were completely relieved in the latter disease.

I will now report a few cases from my own practice to illustrate the remarkable effect of the preparation:

A. G., aged twenty years, had been a robust, healthy young man up to July, 1894; when, while at the seashore, he was seized with severe abdominal pain in the left hypochondriac region. The pain returned from one and a half to two hours after every meal, and was at first felt only for a few minutes. Gradually, however, this time extended; the pain lasted an hour and more, until it finally never ceased completely. Simultaneously with this exacerbation of the pain the general health deteriorated; the appetite vanished, severe thirst took its place, and A. G. lost decidedly in weight. This train of symptoms went on unchecked until, early in October, vomiting and diarrhoea made their appearance, from which the patient had suffered but a few days when high fever set in, forcing him to seek his bed. Here he remained confined for over two weeks, during which his temperature, without any regularity, varied from 102° to 104° F. The discharges were of a foetid odor; the vomited matter, either half-digested food or acid mucus, of the end of the fortnight the fever left him, and he was once more able to be about; but the vomiting, diarrhoea, anorexia and pain, and the loss in weight continued unabated. It was in this state that I first saw him on November 1, 1894.

I had known the patient previously, and was not a little surprised at the fearful change in his looks. He made the impression of a consumptive in the last stages, and even the red hectic spots, almost pathognomonic of that malady, were visible on his cheeks. He could scarcely keep himself in the upright position, so weak was he. The physicians had pronounced his case first one of walking typhoid and later one of acute malaria. There had been no bleeding from the nose, no general malaise preceding the first attack of colicky pain—which had set in abruptly in the midst of apparent health two hours after a meal—and the temperature record also disproved the presence of either fever. Upon physical examination, I could detect no organic disease except an enlargement of the spleen. There were no rose-colored spots; the abdomen was flat and sunken; there were no tympanites, no gurgling sound, and no tenderness whatever in the right iliac fossa. Neither had dysenteric instigated the complaint; the patient never had any bloody discharge from the bowels, no feeling of a heavy weight in the rectum, and intestinal tuberculosis could also be excluded. Nowhere was there felt any pain on pressure, but the pain seemed to radiate from the middle of the descending colon, and to extend thence a little over to the other side, not much beyond the umbilicus. It seemed an ache with colicky exacerbations. The tongue was covered with a thick yellowish fur and evinced a tendency to dryness; no sordes. Sleep very restless. Pains and aches all

* Reports by Dr. M. F. A. Jasenski, Arch. de sci. med., vol. ii, No. 2.
† Berl. klin. Woch., 1893, No. 7.
‡ Wirtsch., 1893, No. 1.
§ Schulenke, Blackstein, and Petkewitsch, Wirtsch., 1892, Nos. 41 and 51.
* Loc. cit.
over the body, reminding one almost of those accompanying
trichinosis. The patient was an Israeliite. Nothing else could
be elicited except the general debility, which seemed to have
seized upon every tissue. Urine slightly albuminous; no casts;
no sugar; otherwise normal; quantity also normal and no
turbulance in meturritation. Temperature, 100-4° F.; pulse, 126.

The discharges were dark brown, highly offensive, fluid,
frothy, and from six to fifteen in number daily. I took a small
quantity with me in a bottle and injected some of it into the
abdominal cavity of a rabbit. The animal seemed restless for
about ten minutes, then appeared as if under the influence of
some narcotic, and in about an hour after the injection it had
four fluid stools in rapid succession, when it was suddenly
seized with spasms and died. Except a congested appearance
all over the small intestines, no lesion was visible at the autopsy.
The bacteriological investigation showed the presence of five
different kinds of micro-organisms, one of them resembling
the bacillus of cholera morbus, but the tests have not yet been
completed.

The patient had been in charge of able physicians; his diet
had been carefully regulated and a great number of drugs
seemed to have been tried in vain. I continued the milk diet
that he had been on for several weeks, but insisted upon the
milk being boiled and drunk hot, and prescribed for him cachets
each containing five grains of beta-naphthol bismuth—three
such cachets to be taken three times daily.

November 2d.—Pain had lessened after the first dose of the
bismuth the day before, and almost ceased after the third dose
this morning, when it was scarcely perceptible. Vomiting
occurred but once yesterday. Tongue begins to clear off; slept
better; pains in joints stopped. The stools have greatly
improved in odor and lost their dark color and frothy appearance.
Had only four discharges since first dose of medicine. Tem-
perature, 99° F.

3d.—No pain; temperature normal; no vomiting, but two
stools of yellowish color. Says that he feels much better
and would like to eat something solid. Tongue but slightly
coated; sleep undisturbed. Ordered toasted white bread with
butter, salt soda crackers, and pouched eggs.

4th.—Appearance greatly changed for the better. None of
the morbid symptoms returned. Tongue clean. Had one
healthy-looking stool, though still soft. Ravenous appetite.
Had a very good sleep for twelve hours, during which he did
not wake once. Permitted more variety in his food.

5th.—Greatly improved in every way. Gained three pounds.
Had no stool. Ordered to take but one cachet twice daily and
to have a dysuria if the bowels did not move.

From this day on his recovery was rapid and uninterrupted,
and two weeks later he had almost regained his former weight
and robust appearance. I induced his parents to go with him
to the mountainous country in Virginia. When he returned, a
month later, he was the picture of health.

J. H., aged thirty-four years. After eating some oysters,
November 11, 1894, was seized with cramps in his stomach and
diarrhoea. Ordered bismuth beta-naphthol, fifteen grains, three
times daily until better, then to take less. Stopped remedy
after but two doses, because of the complete cessation of symp-
toms after second powder. Neither pain nor diarrhoea re-
turned. Recovered.

W. D., aged fifty-four years. On November 12, 1894, called
on me complaining of looseness of his bowels, which had com-
menced a few days before after eating some ice cream and cake.
It always set in immediately after eating. Some eructation.
Tongue slightly coated. No other sign of any disease. Pre-
scribed ten grains of beta-naphthol bismuth. Diarrhoea stopped
after fifth powder, but, as he had a slight relapse a few days
later, I caused him to take for a week five grains of the drug
three times a day, then twice, and ultimately once a day. Dur-
ing the first week his bowels had to be opened several times by
an injection. This constipation ceased with the withdrawal of
the remedy.

C. M., aged sixty-one years. Suffers from frequently recur-
ing attacks of camp diarrhoea contracted during our late war
and evidently due to old ulcerations and thickening of lower
colon. Beta-naphthol bismuth controlled the diarrhoea perhaps
quicker than any other drug (except opium and its prepara-
tions), but proved of no avail in the cure of the complaint.

J. R., aged two months. When, on November 20, 1884, I first
saw this infant a priest present remarked that we should not
torture the little thing, as it plainly was dying. I must admit
I myself had scarcely any hope. When the little girl was nine
days old the mother's breasts had suddenly ceased the secretion
of milk, and the child had been fed in the most injudicious
manner possible. The skin was wrinkled and dry; nothing but
a winthered integument seemed to cover its tiny bones. No ul-
ceration, no specific disease. The baby vomited anything it
swallowed and had from ten to fifteen fluid discharges daily.
No treatment seemed to improve it. I insisted upon a trained
nurse. Every vessel or utensil used for feeding was thorougly
disinfected and kept aseptic; the utmost cleanliness was en-
joined; as diet, nothing but rice water to be given with some
whisky added, and the following powders to be taken inter-
nally:

Bismuth. 8-naphthol gr. ii.
Pulv. aromat. gr. i.
Pulv. Doverii gr. j.
Saccharin q. s.

M. ft. pulvis. Sig.: One such powder to be taken three
times daily.

The improvement was astonishing. Vomiting ceased the
first day; the second the stools, previously of a greenish color,
yeasty and of a sour odor—as in cases of so-called acute dys-
peptic diarrhoea, undoubtedly a misnomer—had assumed a
healthier appearance and their number had been reduced to
four; the third day the disease had actually disappeared. The
baby recovered completely and is as healthy growing to-day as
if it had never suffered from so formidable an attack as the one
described.

M. F., aged five months. On December 3, 1894, I found this
baby, also "artificially brought up," from similar causes afflicted
with the same disease and in nearly the same state as the fore-
going. Having made similar arrangements concerning a nurse,
disinfection, cleanliness, and a suitable diet to those in the first
case, I prescribed the same powders as in J. R.'s case, except
that I substituted the subnitrare of bismuth for the beta-naphthol
preparation. Under its influence the vomiting became some-
what less severe and there were also from two to three stools a
day less, but otherwise no improvement discernible for three
days, when I had recourse to beta-naphthol bismuth. Within
twelve hours after the second dose a more decided change
occurred; on December 7th the improvement was still more
marked, and I increased the dose of the beta-naphthol bismuth
by two grains.

December 9th.—Constipation had set in. This infant also
made a perfect recovery.

I have administered the drug in a considerable number
of cases, but those quoted will suffice to show the effect of
the remedy. The more we have reason to suppose that the
intestinal contents are in a state of fermentation brought
about by the presence of pathogenic bacteria, the more the
toxic products of the latter are responsible for the general impairment of the health of the patient, the more there is evidence of auto-intoxication—the more apparent and the more rapid will be the effect of the beta-naphthol bismuth. It far surpasses that of the older preparations of bismuth. In my opinion, and if I can draw such a conclusion from the cases under my charge, the beta-naphthol bismuth—while the most reliable intestinal disinfectant that we possess to-day, and combining with its antiseptic action an astringent effect—can be given with impunity in doses large enough and for a sufficient length of time to achieve our purpose—the cure of diseases due to the presence of infectious material in the alimentary canal—in infants as well as in adults.

507 Franklin Street.

PHENOMENAL PREMATURE MENSTRUATION.

By D. L. PEEPLES, M.D.,
NAYASOTA, TEXAS.

Miss W. B., a primipara, was delivered with the forceps of a girl on January 25, 1895, at noon. Five days later, or at the age of five days, January 30, 1895, at 2 p.m., the child began to menstruate, which caused much parental alarm, resulting in a second summons for me. Being absent, I failed to arrive until 6 p.m. On my arrival the nurse informed me that she had cleansed and powdered the parts well an hour previously. On examination, I discovered the vaginal canal fairly well filled (in my mind) with undoubted menstrual blood, as it was traceable just as high up as I possibly could determine, without a particle of abrasion, irritation, injury, or inflammation along the vaginal canal whatever. Cessation of menstruation occurred some time during the following night. The breast and genital organs were remarkably well developed at birth, and created some comment among those present, also vivid impressions upon my own mind. Should this little phenomenon continue to have periodic catamenia, I will report the same.

I might further say that the infant is beautifully developed in every respect and enjoys fine health.

The Shelby County (Indiana) Medical Society.—The seventh annual meeting will be held in Shelbyville on Monday, April 8th. The programme includes the following papers: An Address of Welcome, by Dr. H. M. Connelly; Is the Removal of the Rectum for Malignant Disease ever Justifiable? by Dr. J. M. Mathews, of Louisville; A Plea for Surgical Interference in Malignant Growths, by Dr. A. C. Bernays, of St. Louis; The Management of Scarlet Fever and its Sequelae, by Dr. James H. Taylor, of Indianapolis; Gastro-enterostomy, by Dr. R. Harvey Reed, of Columbus, O.; Cholecystotomy, by Dr. Edwin Rick- etts, of Cincinnati; Hysteral Joint Affections, by Dr. P. S. Conner, of Cincinnati; Tubercular Peritonitis, by Dr. L. H. Dunning, of Indianapolis; Quinsy—its Causes and Prevention, by Dr. L. C. Cline, of Indianapolis; The Indications for Operative Treatment in Fibroid Tumors of the Uterus, by Dr. L. S. McMurtry, of Louisville; Gangrene—Report of a Case, by Dr. M. Drake, of Shelbyville. Dr. R. B. Hall, of Cincinnati, will read a paper, the subject of which is to be announced.

The Michigan College of Medicine and Surgery held its commencement exercises in the Detroit Opera House on Wednesday, the 27th inst.
SICKNESS AND TRAVEL.

Serious illness is enough of a misfortune under the best of circumstances, and we need not dilate upon its aggravation, sometimes even to the point of despairing misery, when the sick person is in a strange country, in any place where he is regarded as a stranger, or even away from his own home although in a familiar community. The whole world knows this, but perhaps does not appreciate to what a degree the unpleasantness, to use a mild term, is heightened if the disease is infectious, so that the victim is looked upon as a person to be got rid of, to be expelled from hotels, perhaps to be passed on from one town to another, in a wild and unreasonable spirit of self-protection. If the community had a lively comprehension of the hardships and cruelty that are the consequences, we are sure that the establishment of such hospitals for the subjects of infectious disease as the one now contemplated in New York would be urged forward with great speed.

There is a pecuniary aspect to the subject, and with this the Lancret's Paris correspondent has lately dealt. In a letter published in that journal for March 16th he says: "The first thing the landlord generally does is to order the removal of the sufferer. In addition to this, damages are very commonly claimed to recoup the house for the real or imaginary prejudice caused by the presence of the patient. Now, it need hardly be said that compulsory removal may entail great danger, nor must it be forgotten that the presence of a case of scarlet fever has not unfrequently been successfully concealed from the other denizens of the establishment, in which case it is hard to appreciate the loss of credit or custom incurred by Boniface. The right of the landlord to enforce removal and the payment of damages is rarely contested by the victim, who has then nothing to do but submit. Now the traveling public should know that by a judgment delivered by the Sixth Chamber of the Paris Cour d'Appel on February 1, 1895—a judgment confirmatory of the ruling of the Civil Tribunal of the Seine, dated June 30, 1893—the position assumed by the landlord in such a contingency is untenable. In the judgment it is expressly stated that damages cannot be claimed from a visitor for the trouble and possible loss caused by the presence in the hotel of a member of that visitor's family affected with an infectious disease, provided that the medical attendant delivers a certificate to the effect that risk to life would attend removal to another house. The traveler can resist removal even if the landlord has served him with a formal notice to quit at the very onset of the illness. It is held that the illness is an accident beyond the sufferer's control, and that, further, such an unfortunate occurrence forms part and parcel of the obvious risks attending hotel-keeping. It is ruled, however, that the visitor is responsible for the expenses incurred for the cleansing and disinfection of the premises occupied by him." Still, the writer is of the opinion that in cases where gross extortion is not attempted it is best for the traveler to meet the landlord half-way.

MINOR PARAGRAPHS.

MEDICAL LEGISLATION IN ARKANSAS.

A bill to supersede the State board of medical examiners by county boards has been passed by the Legislature and vetoed by the Governor. If the bill becomes a law, as it may, for the House has passed it over the veto, it will restore the state of things that existed before the present State board was established, and, as we understand it, both that condition and the one now existing can have to do only with non-graduates. A uniform standard throughout the State seems desirable on general principles, but there may be special features of the medical situation in Arkansas that may be adduced as reasons for returning to the old order of licensing. The bill is still pending in the Senate, and we hope it will be considered most thoroughly in that body before the Governor's objections are overriden.

NEW JOURNALS.

In addition to the new medical journals already mentioned by us since the beginning of the year, we have lately received the first number of the Vermont Medical Monthly, published in Burlington, and that of the Canadian Medical Review, a monthly published in Toronto. Each of these new journals is handsomely printed and illustrated, and both appear to deserve success.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 26, 1895:

The New York Medico-surgical Society.—At the next meeting, on Monday, April 1st, Dr. Frederic A. Lyons will read a paper entitled What is Gonorrhea in Women? The following named gentlemen are expected to take part in the discussion: Dr. Robert W. Taylor, Dr. A. Palmer Dudley, Dr. Augustin H. Goelet, Dr. S. Lustgarten, Dr. J. H. Gunning, Dr. L. Bolton Bangs, and Dr. E. E. Ramsdell.

The Mississippi Valley Medical Association.—We have been assured by the president of the association, Dr. Wishard, of Indianapolis, that the preparations for the September meeting in Detroit are in a very promising state of advancement. We feel confident that the meeting will be most successful.

The Kentucky State Medical Society.—The fortieth annual meeting will be held in Harrodsburg, on Wednesday, Thursday, and Friday, June 12, 13, and 14, 1895. Dr. Steele Bailey, of Stanford, permanent secretary, may be addressed for further information.

Change of Address.—Dr. Henry Koplik, to No. 32 West Thirty-third Street, New York.

The Late Dr. Bernard E. Vaughan.—At a stated meeting of the Society of the Alumni of St. Luke's Hospital held on
March 12th the undersigned committee was appointed to formulate and publish appropriate expressions of sorrow in reference to the death of Dr. Bernard E. Vaughan. In accordance with this authorization the committee have adopted the following preamble and resolutions:

Whereas, in the wisdom of Almighty God it has been decreed to remove from among us our esteemed associate Dr. Bernard E. Vaughan, who has been so thoroughly identified with the interests of the society and with the work and advancement of the profession to which we belong; be it therefore:

Resolved, That in the death of Dr. Vaughan we have met with a great loss, that of one whom we valued as a friend and respected for his earnest and uniring work.

Resolved, That the society extend to his bereaved family its sincere sympathy and condolence.

Resolved, That this preamble and these resolutions be entered upon the minutes of the society, and published in the New York Medical Journal and the New York Medical Record.

W. H. Caswell, M. D.,

[Signed.] Thomas S. Southworth, M. D., J. Van Doren Young, M. D., Committee.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 17 to March 23, 1895:

Freck, Enoch B., Captain and Assistant Surgeon, will be relieved from duty at Fort Townsend, Washington, to take effect upon the expiration of his present leave of absence, and will then report for duty at the Presidio of San Francisco, Cal., relieving Wilcox, Charles, Captain and Assistant Surgeon. Captain Wilcox, upon being thus relieved, will report for duty at the U. S. Military Academy, West Point, N. Y., relieving Reynolds, Frederick P., First Lieutenant and Assistant Surgeon. Lieutenant Reynolds, on being thus relieved, will report for duty at Fort Sam Houston, Texas.

Harvey, Philip F., Major and Assistant Surgeon. The leave of absence for seven days granted him is extended twenty-one days.

Porter, Alexander S., First Lieutenant and Assistant Surgeon. The leave of absence granted him on surgeon's certificate of disability is extended four months on surgeon's certificate of disability.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending March 23, 1895:

Bradley, Michael, Medical Director. Ordered before the retiring board, March 20, 1895.

Crandall, R. P., Passed Assistant Surgeon. Detached from the U. S. Steamer Philadelphia, ordered home, and granted three months' leave of absence.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending March 15, 1895:

Godfrey, John, Surgeon. Detailed as chairman board for physical examination of candidates, Revenue Cutter Service, March 6, 1895.

Irwin, Fairfax, Surgeon. To inspect Cape Charles Quarantine Station. March 9, 1895.

Mead, F. W., Surgeon. Detailed as chairman board for physical examination of candidates, Revenue Cutter Service, March 6, 1895.

Grennan, A. H., Passed Assistant Surgeon. To report at Barre for special temporary duty. March 12, 1895.

Gardner, C. I., Assistant Surgeon. To proceed to Angel Island Quarantine Station for temporary duty. March 4, 1895. Detailed as recorder board for physical examination of candidates, Revenue Cutter Service. March 6, 1895.

Stewart, W. J. S., Assistant Surgeon. Detailed as recorder board for physical examination of candidates, Revenue Cutter Service. March 6, 1895.

Cumming, H. S., Assistant Surgeon. To proceed to Boston, Mass., for temporary duty. March 6, 1895.

Society Meetings for the Coming Week:

Monday, April 1st: New York Academy of Sciences (Section in Biology); Morrisania Medical Society, New York (private); German Medical Society of the City of New York; New York Medico-surgical Society; Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association (annual); Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society (annual).

Tuesday, April 2d: Tri-State Medical Society of Iowa, Illinois, and Missouri (first day—St. Louis); Medical Association of the District of Columbia (first day—Washington, D. C.); New York Neurological Society; New York Obstetrical Society (private); Buffalo, N. Y., Medical and Surgical Association (annual); Elmir, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Broome (quarterly) and Niagara (quarterly—Lockport), N. Y.; Essex, N. J. (annual—Newark); Hudson, N. J. (Jersey City); and Union, N. J. (annual—Elizabeth), County Medical Societies; Androscoggin, Me., County Medical Association (Lewiston); Chittenden, Vt., County Medical Society; Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

Wednesday, April 3d: Tri-State Medical Society of Iowa, Illinois, and Missouri (second day); Medical Association of the District of Columbia (second day); New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital, New York; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond, N. Y. (Stapleton); Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

Thursday, April 4th: Tri-State Medical Society of Iowa, Illinois, and Missouri (third day); Medical Association of the District of Columbia (third day); New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Boston Medico-psychological Association; Washington, Vt., County Medical Society.

Friday, April 5th: Practitioners' Society of New York (private); Baltimore Clinical Society.

Saturday, April 6th: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society, New York (private); Miller's River, Mass., Medical Society.

[Note: The text is a transcription of the original document and includes various medical and society meetings listed for the coming week.]
Answers to Correspondents.

No. 453.—According to our latest information, the following are the requirements for the practice of medicine in the different States: Alabama, Arkansas, California, Colorado, Florida, Illinois, Indian Territory, Iowa, Maryland, Minnesota, Mississippi, Missouri, Montana, New Jersey, New Mexico, New York, North Carolina, North Dakota, Oregon, Pennsylvania, South Carolina, South Dakota, Tennessee, Texas, Utah, Vermont, Virginia, Washington, and West Virginia require the passing of a personal examination before the State board of medical examiners. Registration with a county clerk and the presentation of an authorized diploma are required in Arizona, Connecticut, Delaware, Georgia, Idaho, Indiana, Kansas, Massachusetts, and Wyoming. The endorsement of a diploma by a committee of the medical society is required in the District of Columbia and from the State boards of health in Kentucky, Louisiana, Nebraska, and Oklahoma. There are not to our knowledge any legal requirements in Maine, New Hampshire, or Rhode Island.

Births, Marriages, and Deaths.

Died.

Barkeley.—In Chattanooga, Tenn., on Thursday, March 21st, Dr. T. C. V. Barkeley.

Mershon.—In Newark, N. J., on Friday, March 22d, Dr. Richard Blackwell Mershon.

Millin.—In Alden Bridge, La., on Sunday, March 17th, Dr. J. S. Millin, aged sixty-five years.

Ruschenberger.—In Philadelphia, on Tuesday, March 26th, Dr. William S. Ruschenberger, of the navy, aged eighty-eight years.

Taylor.—In New York, on Saturday, March 23d, Dr. James R. Taylor.

Whitman.—In Gardiner, Me., on March 23d, Dr. Caleb S. Whitman.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF CHARITY HOSPITAL.

Meeting of February 6, 1896.

The President, Dr. Adolph Rupp, in the Chair.

Dr. E. Pierre Mallett, Secretary.

Antitoxine and Diphtheria.—The President, in a brief paper with this title, spoke of the failure of so many remedies at one time higgly and plausibly recommended for the cure of bad or severe cases of diphtheria. The most recent remedy, antitoxine, had gained not only professional but lay attention; however, the whole question seemed as yet in an unsettled and unsatisfactory state. He quoted Dr. A. Campbell White, who strongly advocated antitoxine on a basis of a mortality of 23.8 per cent, in a series of four hundred and eighty-six cases. He also cited a series of one hundred and twenty-one cases of diphtheria treated by Dr. Körte (Berlin) with antitoxine, resulting in a total mortality of 31.1 per cent. Körte had divided his cases into three classes—(1) mild, (2) moderately severe, and (3) severe or grave cases. In Körte’s forty-three severe cases there had been a mortality of 59.2 per cent.; in his forty-seven moderately severe cases a mortality of 23.8 per cent., and in his thirty-one mild cases a mortality of 3.3 per cent. As a matter of comparison, the speaker stated that he had lost a fraction less than twenty-four per cent. of his patients treated in private practice during the past thirteen years. Facts such as these justified the doubts of some concerning the value of antitoxine as a specific for diphtheria. Antitoxine might be a specific for bacillary diphtheria—i. e., the diphtheritic symptoms due to the Klebs-Loeffler bacillus. But time and further experience alone could tell us of these matters beyond doubt.

The speaker reported the case of a girl, five years and nine months old, who had been subjected to the antitoxine treatment on the eighth day of the disease (diphtheria). Dr. Benson had injected twenty-five cubic centimetres of antitoxine furnished by the Health Department on January 23rd, twenty cubic centimetres on the 24th, ten cubic centimetres on the 25th, and ten cubic centimetres on the 26th—in all sixty-five cubic centimetres of antitoxine in the course of four days. Local cleanliness had been maintained during this time, and stimulants had been administered, besides iron, and absolute rest had also been successfully maintained. The false membrane in the larynx had continued to form and weep upon the palate. Neither the temperature nor the urine had been influenced, so far as the albumin could indicate change, by the antitoxine. The child had lived five days after the last antitoxine injection had been administered. The speaker thought antitoxine in this case had had no effect for better or for worse.

Dr. A. Campbell White said that he thought one must first believe in bacteriology before one believed in the antitoxine. If one was not satisfied that the bacillus was at the foundation of all cases of true diphtheria, one could hardly believe in any such treatment as that with an antitoxine which was derived from this bacillus. In studying the effect of antitoxines upon diphtheria one should thoroughly appreciate the different conditions that might arise independent of the infection. The rule in diphtheria was a low temperature. In children suffering with laryngeal stenosis the temperature would rise from the mere effect of the stenosis; and in those having diphtheria there were so many conditions that might cause a rise of temperature that it was difficult to determine how much effect antitoxine would have on the temperature. He thought it had no effect on the temperature, unless it was to cause a short rise immediately after the injection, which was probably due to the injection of a large quantity of fluid into the patient. In the case mentioned by the previous speaker the amount of the solution given showed that it had been a mild one, and all the statistics showed that more favorable results were obtained from the stronger solutions. Behring’s solution No. 3 he had seen used several times, and the patients had all recovered; the No. 2 he had never seen any marked effect from, although the patients had recovered; and as to the No. 1, many patients treated with it had died. Of Aronson’s solution there was only one strength, and it produced decided effects some nine or ten hours after the injection. The injection was followed by a slight rise of temperature, the pulse improved, the symptoms of stenosis lessened, and there was a marked change in the general condition of the patient. A child sick at the time of the injection in the evening would be surprisingly well on the following morning. The membrane disappeared within eight or nine days. He had seen about a hundred cases treated, and in none of them had there been any complication that could be attributed to the antitoxine, unless it might be a slight rash that disappeared in a few hours. He thought if antitoxine had any good effect at all it must be a specific. Almost all the criticism against antitoxine came from those people who had had but a limited experience, and all having a large hospital experience, seeing its effect in some two or three hundred cases, spoke favorably of this treatment.
Dr. Louis Fischer agreed with the previous speaker that the greatest amount of skepticism was shown by those who had the smallest number of cases. He thought one should be particular as to the kind of antitoxine used, as he recently had had three different kinds sent to his office. Antitoxine when injected gave no local reaction; it worked antisepically, there was no elevation of temperature or chill, nothing to show that anything had been injected, which was not the case with injections of tuberculin for tuberculosis. In tuberculin injections one always waited for paroxysms of fever, chills, perspiration, etc., to subside before giving a second injection. In the use of antitoxine nothing of the kind occurred unless through some mistake. The low temperature in the most malignant cases of diphtheria he thought an important point. The temperature merely showed how much active septic matter there was in the system; the greater the amount of septic matter, the higher the temperature at times. He referred to Professor Baginsky, who had made a special study of the urine and found many cases in which the albumin was increased, and believed it might be due to the antitoxines. He asked Dr. White if he had noticed that the antitoxine had modified the membrane. He thought the first evidence of the effect of the remedy was the melting away of the membrane. While the membrane was merely a local manifestation of the trouble, abroad it was looked upon as an important factor to gauge the course of the subsequent treatment of the case. Behring's solution No. 1 was used only for prophylactic purposes; Behring's No. 2 for mild cases; Behring's No. 3 for malignant cases of diphtheria, and he had seen some very good results from it. In the case reported by the president, sixty-five cubic centimetres was an enormous dose; he had never used more than twenty-five. He did not rely only on the antitoxine, but included local antisepsis in every case. Colomel was the best cathartic. He thought if the president would try Behring's antisepsic, or Aronson's, and use it freely, he would have much better effects. Aronson made one Heilerum for testing purposes and one for prophylactic purposes; of the Heilerum five cubic centimetres injected in the interscapular region was equivalent in strength and action to ten cubic centimetres of Behring's No. 2. It was only necessary, however, to observe the patient's general condition after the first twenty-four hours following the injection; if we found any improvement, then it was not necessary to reinject, but if no visible improvement in pseudo-membrane—pulse, temperature, condition of skin, urin, expression, or appetite—took place, then he advised by all means to again inject, and, if possible, double the first dose. Impurities in the serum, due to glanders in the horse and other foreign impurities, had caused eruption of various kinds from an erythema simplex to a purpura hemorrhagica.

In this class of cases great care was necessary, and they should be continuously treated with antitoxine. Stimulation should not be begun in all antitoxin cases, rather only where the heart and pulse showed extreme feebleness.

Dr. W. R. Jonsson spoke of cases he had seen treated with Behring's solution for immunization. One of the patients had recovered, and there had been no local effect from the injection. Another patient had gone into a period of excessive excitability, approaching convulsive movements, which might have been due to excessive stimulation or to the antitoxine; in the course of thirteen or fourteen hours the patient had died. A third case had occurred in the same family, in a child two years and a half old; the child had had very severe croup and dyspnoea. The speaker had been asked in to intubate, which he had done, and a single injection of a drachm of Behring's six-hundred-antitoxine-unit solution had been given. The temperature had gone down from 104° to 101·5° by the next day; at the end of the sixth day the tube had been removed, the progress of the disease had been uneventful, and the child had recovered. He asked as to the use of the protective solution for a cure, and also as to its possible deleterious effect, and the size of the dose of that and the other solutions of antitoxine.

Dr. Wurz stated that he had seen no marked effect upon the membrane causing it to disappear immediately. In the case he had reported, treated with Aronson's strong solution, the membrane had not dis-appeared till the ninth day. There had been a marked diminution of the swelling, but the stay of the membrane had not been shortened probably more than a day. The skin injections had been based upon the general condition of the patient—whether the glands of the neck had been larger or smaller—and the condition of the pulse. He believed it prevented extension of the growth, and this had been very marked in the tracheotomy and intubation cases; in these cases the patients had almost invariably died from the extension of the membrane, and the patients treated with the antitoxine had not.

The Pathology and Clinical History of Influenza.—Dr. R. C. Newrox read a paper on this subject. He stated that the first accurate record of the disease had been in the year 1510, and that it had reappeared at intervals of about twenty years. In the great epidemic of 1889—90 it had traveled from St. Petersburg to New York in six weeks, which had surpassed all former records; its speed in crossing the earth had increased with improved facilities of travel. The disease was difficult to diagnosticate, as the symptoms resembled those in other fevers. Typhoid fever, cerebro-spinal meningitis, and typhus fever would soon reveal their true nature; but dengue or dandy fever was so like the grippe that some thought it the grippe of hot climates. Bacteriology was a great help, and the bacillus of Pfeiffer was probably the true cause of the disease. Animals were affected, and the contagion was alleged to spread from them to man. The connection between cerebro-spinal fever, pneumonia, and influenza had been pointed out more than once. In short, both pneumonia and cerebro-spinal fever might be produced by various bacteria. The grippe bacillus, for instance, might produce either or both of them, as well as the typhoid bacillus. The connection between influenza and cerebro-spinal fever had been alluded to in the Transactions of the American Medical Association in 1866, when it had been stated that the "spotted fever," which occurred at the same time as the grippe, resembled it so closely that many thought the contagion of the epidemic influenza in its intensity might produce spotted fever. In influenza the virulence of all micro-organisms was raised to the highest degree. This fact explained the frequency of secondary infections, giving rise to the various complications and sequelae. Old nervous troubles were apt to be relieved and to burn with increased energy. An old and supposedly cured syphilitic would return to plague its possessor. One specially noticeable feature of the complicating lesions of this disease was their tendency to bilateralism, orchitis and ostitis particularly showing this, which was a powerful proof of its microbic origin. Of the nervous lesions, every form of nervous disease and every form of insanity seemed to be caused by grippe. Autopsies were rare, as the disease was seldom fatal, but two had been reported in which death had occurred as a result of brain lesion; in both, hemorrhagic foci had been found in the white and gray substance of both hemispheres. In eleven other autopsies intense hyperemia of the pia mater at the base of the brain had been present; the arteries had been distended and the consistency of the brain and spinal cord had increased. It was believed that this hyperemia was more than an evidence of vaso-motor disturbance, and pointed to the natural association between influenza and epidemic cerebro-spinal meningitis. The contagion was very
It was a wonderful and interesting disease, and the prospects of its true etiology, pathology, and diagnosis being established on a sure foundation by the bacteriologists, was a matter for profound congratulation.

The Symptomatology and Treatment of Influenza.—Dr. W. L. Strowell, in a paper on this subject, stated that the poison of influenza interfered with the functions of many organs of the body and gave rise to a great variety of symptoms. The leading ones were referable to the respiratory, nervous, or digestive system. The disease was essentially a catarrhal, hence sneezing, coryza, and irritation of the throat were early symptoms. In one it took the form of exudative myalgiditis, in another laryngitis, sometimes suppurative angiditis. In weak persons at the extremes of life the abundant secretion caused pulmonary collapse after coughing and started bronchitis or lobular pneumonia. Laryngitis in adults led to aphonia and harsh voice sounds, in children it was usually catarrhal and caused croaky breathing. Enlargement of the parotid glands, oritis with suppuration, and enlargement of the upper cervical lymphatic glands were observed. The digestive disturbances were loss of appetite and nausea and vomiting. The bowels were rarely normal, constipation being present early and diarrhea coming later, seemingly to mark a crisis and return to health. The symptoms of the nervous system were stupor, intense headache, vertigo, languor, depression of spirits, lack of interest in surroundings, and general mental numbness; children often had convulsions. The pains were intense and varied only in seat and degree. Some had trifacial neuralgia, others pains in the neck, articular pains, and a feeling of soreness everywhere; pains in the chest like intercostal neuralgia, pains in the stomach and bowels, and cramps in the legs. Convulsions, delirium, and stupor were most common in the young; menchelobia, less pain, but more pulmonary trouble, seemed to fall to the aged. High temperature indicated complications. A weak pulse was common in most cases of poisoning. The kidneys were inactive, while congestion was everywhere present and normal secretion lessened; the urine was high-colored and of high specific gravity, and might contain albumin. The speaker referred to cases he had seen with complications of syphilis, pertussis, and erysipelas of the face and leg; one case of phthisis had been thought to have originated with an attack of la grippe; one woman pregnant at the third month had aborted; a nurse had been seized with measles immediately after an attack of the disease; another had had pleuro-pneumonia and had died.

Treatment.—Nutrition must be maintained and elimination promoted, from the lungs by expectorants, from the digestive tract by cathartics. Phenacetine, antipyrine, and acetanilide were best for the headache. The old-fashioned diuretics and diaphoretics relieved fever and joint aches. Salicylate of sodium and carbonate of ammonium in malting were other remedies. For slow convalescence, beef juice, eggs and milk, wine whey, and malt with iron or cod-liver oil were useful. Embrocations were helpful, using alcohol one night and olive oil the next.

With advancing civilization the scourge had quickened its pace and covered the globe in a fraction of its former time. Its mortality was the same under nineteenth-century treatment as hundreds of years ago, few dying directly of the disease, but many of secondary complications. The aged suffered most and children least, because the latter were usually free from organic disease of heart, lungs, or kidneys. The one thing discovered was the cause—the bacillus found by Pfeiffer and Canon—but how to meet and annihilate this invader remained to be demonstrated.

Dr. Henry S. Oppenheimer spoke of three cases that he had seen lately, all in young men. One, a draughtsman, aged thirty, had complained of seeing double and growing dizzy. On examination he had about a tenth of normal vision in the right eye; his field had been narrowed. The pupil had been dilated widely. The motion of the eye upward had been very painful due to the stretching of the inferior rectus muscle of that eye, which had been parietic. The nerve had been lazy and the retina between the disk and the macula had also been a little opacificed, with some minute striation. The eye had been more prominent than its mate. The diagnosis had been retro-bulbar neuritis, or inflammation of the optic nerve in the orbit back of the eye. As to causation, there had been nothing except that the man had had the grippe, but not so severe that he could not work. There had been no history of syphilis. The man had been nervous, his pulse rapid and not strong; and there had been no murrain. The second case had been that of a barber, aged twenty-four. There had been ecdysis in the lids and conjunctive of both eyes. He had with the left eye a fourth of normal vision. His pupil had not been dilated, and he had presented exactly the same appearance of the fundus as in the previous case. The nerve had been perhaps a little more affected, and the retina between the nerve and the macula not so much as in the other case, but still there had been a little haziness. The third case had been that of a young man, aged twenty-seven, whom the speaker had known from childhood. He had had the grippe for two weeks, suffering mostly from muscular pains in the back and side. On examination, his vision in the right eye had been reduced to a tenth, his color field had contracted to about ten degrees from the fixation point, but had been perfect within this limit; he could distinguish shades even. There had been a tremendous swelling of the optic disk, and of the retina near it. There had been numerous small hemorrhages within this region, and the veins had been large and very tortuous. The pupil had been normal, as had also been his field for white. Now, in these three cases there had been neuritis of one eye only. The second eye in each case had appeared normal. There had been no history of syphilis in any one of these cases, and only in the first one had a suspicion of it been created by the fact that the man's wife had had six children, five of whom had died in infancy. The third men had had grippe, and that had been the only evident cause of the neuritis. In the second case the man had been coughing, and, being a rather plethoric fellow, this probably had caused the hemorrhage under the skin and conjunctive.

Dr. Beverley Robinson thought the grippe a queer sort of a disease that showed its manifestations in a variety of ways. He spoke of the need of a specific to allay the poison as antitoxine was alleged to do for diphtheria. For the last two years he had combated the disease by keeping the patients in creosote vapor. It was an antiseptic that could be taken in large doses without harm, while carbolic acid, if, inhaled by the individual, would be injurious, and mercurial did not have the antiseptic power of creosote. If taken in the fluid form it would upset the stomach and might affect the kidneys, but if vaporized it would not affect the stomach. He had used it in many cases of croupous pneumonia with good results. If the respiratory passages were rendered aseptic the micro-organisms could not live there. He thought scientists only followed the empirists. The scientist might give the explanation of why a drug was helpful, but the empiricist was the discoverer of the remedy.

Dr. F. M. Warner spoke of the phases of the disease in children—the inflammation of the respiratory passages and catarrhal inflammation of the gastro-intestinal tract, particularly laryngitis and gastro-enteritis. In one case the laryngitis had
been so severe that it had been a question whether there had not been a croupous exudation existing. The child had made a recovery without intubation. The gastro-enteritis had been so severe in one case that after a lapse of forty-eight hours the child had been almost in the condition of one after a violent attack of gastro-enteritis in the hot summer season, had lost a great many pounds of flesh, and had had constant liquid movements. Nephritis was pretty constantly present, but seldom discovered, because the urine was seldom examined in young children. He spoke of using creosote vapor where there was a cough following the gripe, where the cough did not yield to other remedies. He used a fifty-per-cent. solution of creosote and terebene by means of Dr. Robinson's inhaler, and also gave creosote internally.

Dr. Robinson stated that he used creosote in the following way: He vaporized it in the room, made a solution of a drachm of the creosote to an ounce of alcohol, and added a teaspoonful of this mixture to a pint of hot water, keeping up the inhalation for twenty-four or forty-eight hours at a time.

Dr. W. L. Carr spoke of the inflammatory troubles in children connected with catarrhal diseases of the respiratory tract. He referred to two recent cases in children. One had had a naso-pharyngeal and bronchial catarrh following an attack of the gripe. The child's respiration had been 68, pulse 148, temperature 101.4°. There had been quite a little catarrhal condition and bronchitis. What had been especially noticeable had been the absence of respiratory murmur at the base of the left lung. The speaker had ordered a hot bath, counter irritation of the chest, and a dose of calomel. On the following day the temperature had fallen two degrees; within twenty-four hours the temperature had been normal. There had been a continuity of some mucous sounds, but no fine rales of any kind. Within forty-eight hours the child had had acute pneumonia of the left side and had gone through a regular course. The other case had occurred in a syphilitic child. There had been at the right base the absence of respiratory murmur, with almost the same history, the temperature (102.5°) had dropped to normal without any medicine or bath. At the end of fifty-two hours the child had had a temperature that had run up suddenly to 105° F. The child had had pneumonia followed by coryza, from which it had been convalescent. The peculiarity had been the absence of respiratory murmurs and the occurrence of the pneumonia after the temperature had been normal for forty-eight hours. He thought antiseptics in almost all cases were of service locally, and advised the use of irrigation with mild alkaline solutions. Creosote and eucalyptus had proved beneficial when used for inhalation from a croup kettle.

**Book Notices.**

*The Elements of Pathological Histology*; with Special Reference to Practical Methods. By Dr. Anton Weichselbaun, Professor of Pathological Anatomy and Director of the Institute of Pathological Anatomy in the University of Vienna. Translated by W. H. Dawson, M. D. (Dub.). Demonstrator of Pathology in the Royal College of Surgeons, Ireland, etc. With Eight Plates and a Large Number of Illustrations in the Text, some of which are Colored. London and New York: Longmans, Green, & Co., 1895. Pp. xxviii to 456.

In translating this work Dr. Dawson has arranged the text in chapters in which the practical portion is printed in smaller type than the descriptive, so as to facilitate reference; he has interpolated the exact zoological names of the animal parasites and made some other insertions in relation to terminology; and he has introduced descriptions of the method of fixing specimens for section cutting by imbedding them in frozen gum, and has described Bevan Lewis's modified fresh method of examining the brain. These are the essential differences between this work and the German edition, that appeared some three years ago.

The author's aim in preparing the work was to provide a guide in which the inexperienced might find brief and concise descriptions of the doctrines of pathology and of the most useful and practical methods for its investigation. Accordingly the volume is divided into three parts, the first dealing with the general methods of investigation, the second with general pathological histology, and the third with special pathological histology.

The first part describes the histological and bacteriological methods of investigation, including the methods of transmission of pure cultures of micro-organisms to animals. The second part describes the retrograde and progressive changes in tissues, neoplasms, and parasites. In the third part the organs are separately considered, the different chapters treating of the blood; the circulatory apparatus; the spleen, the lymphatic and the thoracic glands, and suprarenal capsules; the digestive apparatus; the liver, bile-ducts, and pancreas; the respiratory apparatus; the urinary apparatus; the generative apparatus; the nervous system; the organs of locomotion; the skin; the eye; and the ear. At the end of each chapter the best methods of examination are described, and their diagnostic value is specified.

In the examination of the tissues of the nervous system the author prefers Weigert's stain, Pol's modification of the same, Heidenhain's method, and Adamkiewicz's method. We should have been glad to learn the author's or the translator's experience with formalin.

The chapters on the eye and the ear are noticeable on account of the detail with which the pathology of diseases of these organs is described; too often it is scarcely referred to in textbooks on this subject.

The illustrations are beautiful and their number is such that the student should never be at a loss in regard to the appearance of any pathological condition.

The volume is a useful addition to our text-books, and the excellence with which the translator has fulfilled his task makes the work pleasant reading.

The increase of general paralyses in frequency of occurrence makes that disease a matter of great interest to the profession. This little volume does not purport to do more than give the essential data in regard to the symptoms, progress, duration, pathology, and treatment of the disease, and it may be recommended as a thorough review of our present knowledge of the subject.

*The Middlesex Hospital.* Reports of the Medical and Surgical Registrars and Pathologist for the Year 1893. Dr. F. J. Wethered reports that during the year 1,323 medical patients were treated, of whom 1,091 were discharged, 52 were transferred to the surgical wards, 169 died, and 128 remained in the hospital on the first day of January, 1894. The general table of diseases is arranged in accordance with the classification recommended in the Nomenclature of Diseases.
of the Royal College of Physicians. There are résumés of the histories of fifty two cases of diphtheria, in which there was a mortality of 42.3 per cent., of twenty-one cases of enteric fever, in which there was a mortality of nineteen per cent., and of cases of influenza, empyema, pneumonia, aneurysm, typhus, and some rare diseases.

Mr. C. E. L. K. Hudson reports that 2,749 surgical patients were treated, of whom 2,171 were discharged, 303 died, and 275 remained at the end of the year. The average duration of treatment was 22.8 days. There are abstracts of the histories of cases of hornia, perityphlitis, intestinal obstruction, gallstones, laparotomy, and compound fracture, and of 118 operations on the kidney performed during fourteen years. There is also a summary of the gynecological work performed in the hospital.

The volume affords excellent evidence of the good work done by the medical staff of the institution.

The medical profession is indebted to Dr. Noyes for editing a work that deserved to be put into English dress almost two years ago. It is eighteen years since Foerster first dealt with the subject in von Graefe and Snaemisch's Handbuch of Ophthalmology; his essay was followed by that of Rampoldi; then Jacobson, in his work on diseases of the eye, devoted the second part of the volume to the relation of the eye to general disease; and finally Berger published his study on the same topic.

This important subject is scarcely referred to in any of the text-books on diagnosis, on theory and practice of medicine, or on diseases of the eye. As the editor very truly says, the alliances between the eye and the rest of the body are so adumbrably traced throughout this volume that it will be hard to decide whether the general practitioner or the ophthalmologist is under the greater obligation to the author.

As might be supposed, almost half of the book is devoted to diseases of the nervous system. After a description of the anatomical course of the nerves of the eye, the disorders in their domain are considered, and this is followed by a narration of the ocular symptoms in individual diseases of the brain and its membranes, of the spinal cord, and of the nerves, and in the functional neuropsychoses.

It is not apparent why, in the chapter on diseases of the skin, eczémas, which is an infectious disease, should be treated of; and if lepra is considered in the chapter on chronic infectious diseases, why is not lupus? Insolation seems to be absolutely out of place in this chapter, especially as it is referred to in the chapter on diseases of the nervous system.

Separate chapters are devoted to diseases of the digestive, of the respiratory, of the circulatory, of the urinary, and of the sexual organs. The final chapters are devoted to the influence of poisons and infectious diseases on the eye, and to that of constitutional diseases.

Occasionally a repetition of facts occurs, but these are unimportant faults in a work of this kind. The volume should be carefully studied by all physicians, and it demonstrates how necessary it is for the physician, and especially the specialist, to have a knowledge of general medicine as well as of the specialties.

The able author of this work has taken occasion in the preparation of this second edition to add a new chapter on the analysis of symptoms, to contribute additional text to the chapter on chronic purulent inflammation of the middle ear, and to rewrite the chapter on operations on the mastoid process.

The chapter on the analysis of symptoms is likely to prove very useful to the student. It deals with symptoms of disturbances of the function of hearing, including subjective noises, the sensation of something moving in the ear when the head is moved, the sensation of pressure or fullness in the ear, unnatural resonance of one's own voice in the affected ear, pulsation or throbbing, itching or soreness, pain, discharge from the ear, vertigo, and a sensation of numbness.

In the revision of the chapter on diseases of the mastoid process the author maintains the superiority of the chisel to the drill in the operation of opening the mastoid antrum, and he takes issue with MacKenzie, who, in his magnum opus, advocated recourse to the drill alone. While aural surgeons are generally in favor of the use of the chisel, the general surgeons are by no means partial to it; to the reviewer it seems that, in the hands of an inexperienced operator, the drill is less likely to cause injury than the chisel.

The manual is a comprehensive and careful piece of literary and professional work, and deserves the popularity that has been accorded to it.

This little book is intended to be a compact work of reference as to doses, abbreviations, synonyms, the management of emergencies, the symptoms and classification of skin diseases, diseases of the digestive system, miasmatic diseases, and fever, favorite prescriptions, and various other matters of interest to physicians. It contains a great deal of useful information.

Mr. Rake calls attention to the fact that in aseptic surgery the great object aimed at is that everything that comes into contact with the wound shall be absolutely free from germs that are pathogenic in man or that are putrefactive; while in antiseptic surgery the wound and everything coming in contact with it is impregnated with some antiseptic solution. The former, therefore, is the cheaper method in hospital work, the chief cost being in the amount paid for apparatus. A Lauten-

413

(40 yards), triacet some three dollars a piece, and moss (Sphagnum cusubflata) about twenty-five dollars a bale of 250 pounds. The translator also refers to the fact that the chief obstacle to the efficient carrying out of spective methods is the frequent change of house surgeons.

Dr. Schimmelbusch describes the modes of infection, of dis-infection, and of sterilization; the preparation of dressings, sponges, suture, and ligatures; the aseptic drainage of wounds; the aseptic use of hypodermic and aspirating needles and catheters and bungs; the details of the operating and sick rooms; and the improvisation of aseptic dressings for emergencies.

The author and the translator have given the profession a very useful and reliable guide to the details of aseptic surgery.

In the sixth edition of this well-known work the author has not found it necessary to make any additions. It is a satisfactory, though not exhaustive, manual that will be found very useful by students and practitioners.

BOOKS, ETC., RECEIVED.

The Elements of Pathological Histology; with Special Reference to Practical Methods. By Dr. Anton Weichselbaum, Professor of Pathological Anatomy, and Director of the Institute of Pathological Anatomy in the University of Vienna. Translated by W. R. Dawson, M.D. (Dub.), Demonstrator of Pathology in the Royal College of Surgeons, Ireland, etc. With Eight Plates and a large Number of Illustrations in the Text, some of which are Colored. London and New York: Longmans, Green, & Co., 1895. Pp. xxv-7 to 456.

A NEW ADJUSTABLE NASAL SAW.

By HERMAN L. ARMSTRONG, M. D., SURGEON TO THE CENTRAL THROAT HOSPITAL, BROOKLYN.

All rhinologists who have had any considerable experience are cognizant of the fact that operations in the nasal lumen with cutting forceps, gonge, chisel, trephine, or drill are not attended with the best results, from the fact that the parts are left in a mere or less rough and nodular condition, which Nature, in her efforts to repair, will build up as high as the highest point left by the operator, and as a consequence we find that after the parts are thoroughly healed we have no improvement in the original condition. It is needless for me to eulogize the nasal saw, as all rhinologists recognize this instrument as being the only one by which exostoses or enchondromatosous growths can be removed and followed by a perfect result.
Feeling the need of a saw that would answer all requirements, I have devised the one here illustrated; it can be adjusted at five different angles, and is readily converted into an instrument either with straight, up-cut, or down-cut blade; it is thoroughly aseptic, and may be folded and placed in a bag with other instruments without danger of being dulled or injuring the others. It is made in a neat, compact, and durable form by George Tiemann & Co., New York.

MISCELLANY.

The Proposed Indian Pasteur Institute and Vivisection.

The February number of the Indian Medical Gazette contains a very interesting article on this subject by Surgeon-Colonel Harvey, in regard to the action of the Bengal Branch of the Anti-vivisection Society in opposing the proposed Pasteur Institute for India. Dr. Harvey sums up the arguments for and against experiments on living animals, and hopes that doubters may be convinced that such experiments are not only justifiable but necessary. The question, he says, may be looked at from two sides, the ethical and the scientific, and may be arranged in two divisions: Vivisection proper, which alone involves cutting operations on living animals, causing their death; and experiments on living animals without cutting operations, involving temporary pain or discomfort only. These, says Dr. Harvey, are all bracketed together under the head of vivisection by the opponents of experimental research, who base their opposition on the following grounds: 1. Animals have rights as well as men, and one of these rights is to be saved from cruelty. 2. The experiments lead to little or no useful or practical results. 3. Even if they did, the cruelty which they involve makes them unjustifiable, since man has no moral right to inflict cruelty for his own advantage. 4. The experiments have a demoralizing effect on those who perform them.

The main arguments on the scientific side are: 1. The experiments are necessary for the advancement of knowledge, and this necessity is recognized almost without exception by the medical profession. 2. They have, in fact, “been of inestimable service to man and to the lower animals, and the continuation and extension of such investigation are essential to the progress of knowledge, the relief of suffering, and the saving of life.” 3. They are conducted under Parliamentary restriction, without cruelty, and with the least possible suffering. 4. The statements of the antivivisection party are inaccurate, exaggerated, and misleading. 5. Suffering and sacrifice are facts in Nature which no declamation can eliminate, and the rights of man are superior to those of animals. 6. The experiments have no demoralizing effect on those who perform them.

We have to deal, says Dr. Harvey, with questions of fact, with a matter of opinion, and, above all, with the meaning of words. Vivisection implies the dissection of live animals without anaesthetics. The term, he thinks, should not be applied to experiments performed under the influence of chloroform; it does not apply to the killing of animals by poison or by snake-bite, and still less to the feeding of them with particular varieties of food or to inoculating them with disease germs, and, although the antivivisection party objects to all these, they have no right to speak of them as vivisection. Cruelty, too, is another word which they have vested with an entirely new meaning, and much of the bitterness of the controversy has been due to confusion arising from this difference in meaning.

According to the antivivisectionist, as represented by Miss Power Cobbe, says the author, cruelty is “the voluntary infliction by a moral free agent on a sentient being of severe pain, not beneficent to the sufferer, and not authorized by justice.” It is obvious that, according as we use the word in one sense or the other, both parties are right, for while the experimenters do not experiment without good reason, and have no disposition to give unnecessary pain, the experiments are certainly not beneficent to the sufferers, although they are often of the utmost benefit to men and to animals as a whole. On the strength of this novel definition—entirely unknown to the English language—the antivivisectors denounce the experiment as atrocious cruelty, diabolical practices, hellish actions, and so on, branding the experimenters as monsters, hold them up by name to the execration of mankind, send anonymos abuse to their wives—in short, forget the courtesies of controversy and the common decency of life.

Miss Cobbe, he continues, gives a clever classification of subjectively defined cruelty into ignorant, careless, wanton, malicious, and interested cruelty; in “wanton cruelty the person causing pain for the sake of the emotional excitement which he derives from the spectacle,” in “malignant cruelty the cruel person causing pain from hatred of his victim, and taking direct pleasure in his pain,” in “interested cruelty, the cruel person causing pain, with or without reluctance, for superior purposes of his own or the benefit of third parties,” and she considers interested cruelty “the most dangerous.” It is quite clear, then, says Dr. Harvey, that the assertions of atrocities so often made by the antivivisection party require to be received in a special sense, and that they apply the word cruelty to the experiments by a new standard which they do not use for the rest of the world. It is of the greatest importance to keep this constantly in mind.

Dr. Harvey answers the main arguments in their order, and with regard to the rights of animals, he says, the physiologist and the physician are quite willing to accept the dictum that animals have rights, and that to be saved from cruelty is one of them. But man has rights as well as animals, and his rights are paramount when a good reason can be given for subordinating their rights to his. With regard to utility, it is commonly contended that the experiments lead to few or no useful results, that they are confusing and misleading, hindering and not helping the advance of knowledge. It is surely for the medical profession, says the author, to determine whether they have been helped by such experiments, and their testimony must outweigh that of women and clergymen not specially trained in physiological or surgical knowledge. The discoveries of the circulation of the blood, the physiology of respiration, the functions of the spinal nerves, of the liver, and of the thyroid gland, the localization of the motor areas in the brain, the foundations of modern physiological knowledge, says Dr. Harvey, have all been founded on the Baconian principle, “Interrogate Nature.” By recent improvements, also, many operations have been to a great extent freed from risk and new ones rendered possible. But for recent experiments on monkeys no surgeon could have diagnosed accurately the site of a tumor in the brain. By the sacrifice of a few sheep, pigs, and fowls, anthrax, swine-fever, and chickens have been brought under control, to the enormous benefit of the animals themselves and to the great profit of the farmer. It is stated, he says, although he does not vouch for the figures, that the mortality from anthrax has been reduced from eighteen to one per cent., and that about 3,500,000 sheep and 600,000 cattle have been inoculated against the disease in France alone, and that the money value of those saved is about seven millions of francs. Dr. Harvey gives this as an example of the utility of experiments, a utility which is now admitted by the antivivisectionists themselves. Miss Cobbe, says Dr.
Harvey, defines cruelty as the infliction of severe pain not benefi-
tial to the sufferer, and she absolutely refuses to admit that it can be justified by utility. "If vivisectors," she says, "have already made, or shall hereafter make, discoveries tend-
ing directly and importantly to relieve our bodily pains, even
then would vivisection, I ask, stand justified? Not so, my friend,
as sure as night follows day." She is here clearly committed to the statement, says the author, that the infliction of severe pain not beneficent to the sufferer can not be justified on the plea of utility, and if this rule is true it must be universally applied, and leads to some strange conclusions. Man constantly inflicts severe and unnecessary pain not beneficial to the sufferer for his own conve-
nience and sport. For the sake of pecuniary profit many cruelty
eaners are committed, such as the skinning of animals alive to
get the fur in better condition, the injection of air under the
skin, etc. The vagaries of fashion and the personal vanities of
men and women are the cause of much pain. For the gratifi-
cation of his appetite man does not hesitate to unsow fows, sub-
ject innumerable geese to grave disease, boil lobsters alive, and
do other acts quite as "cruel" as any done by the physiologist.
If the experimenters are guilty of gross cruelty, says Dr. Har-
vray, the fact that others are also guilty would not excuse them;
the point to be emphasized is, that, according to the anti-
vivisection definition, they are on a level with the rest of mankind.

With regard to the supposed "demoralizing" effect of the
experiments, says the author, it is much insisted on in the writ-
ings of the antivivisection party. They have supposed that a
man who does things so cruel must necessarily become thor-
oughly heartless, altogether inhuman. There are no keener
fishermen than the clergy, he remarks, but we do not find them
demoralized or converted into monsters. The author does not
deny that many cruelties have been performed by experiment-
ers; cruel men may exist in the medical profession as else-
where, and should be dealt with in the same way.

Dr. Harvey remarks that he has wasted through a mass of
the literature of the antivivisection party, and the perusal, he
says, makes him understand how the agitation is created and
maintained. The writer's imagination in harrowing de-
scriptions, and ladies ignorant of physiology, ignorant of sci-
ence, are horrified accordingly. The writers themselves are to
some extent self-deceived. They "shrink," as we have seen,
over the "agonies" of the frog, while justifying the torture of
the suffering salmon; they eat their yeal and faire gris con-
tentedly, and bemoan the woes of the rabbit used for the advance-
cement of learning, while ignoring the fact that thousands of
these rabbits are killed in gins and snare. It seems to the au-
thor that, from a careful perusal of this literature, the greater
part of the opposition to experiments is founded on ignorance,
on taking for granted as truth untrue or grossly exaggerated
statements. Much of it, he says, is sentiment, much unreal.

Dr. Harvey hopes that what he has said will be sufficient to
convince the public that scientific research is necessary to the
advancement of knowledge, that it involves no cruelty, properly
so called, and very much less pain and suffering than many
other things sanctioned by reason and by the universal custom
of mankind; that it is guarded from abuse by sufficient legal
restrictions; and that sensitive and humane men may lend it
their moral and material support with the clearest of con-
sciences. A branch of the Pasteur Institute is needful in India,
he says, not only in the interests of those bitten by rabid ani-
imals or infected with diptheria, but for the investigation of
the Indian diseases of men, animals, and plants.

The Treatment of Metrorrhagia.—The Presse médicale
for March 9th contains an article on this subject in which the
writer remarks that there is no practitioner who has not often
had to combat rebellious hemorrhages dependent upon the
alterations of the uterine mucous membrane in cases of simple
domatitis as well as in those of intraperitional or submucous
fibroma.

Curetage, which is too often employed without definite
indications, is frequently ineffectual, he says, and, if numerous
methods of treatment have been successively proposed in these
cases, we can but see in that fact an evident proof of their too
frequent ineffectuality.

Among the hemostatics lately experimented with it seems
that antipyrine should have some importance attached to its
employment; it has, in addition, the great advantage of being
manifestly antiseptic. Chouppé, Hochard, and Chéron have
used antipyrine internally with success for uterine hemor-
ragh. It is, however, by topical application that it appears to
give the best results. In order to render the local applications
easier, M. Labadie-Lagrange conceived the idea of associating
antipyrine with a substance dissolving at a relatively low tem-
perature, and for this purpose he selected salol because of its
antiseptic properties and its liquefaction at 192°.
The method is very simple, and the liquid may be prepared at a moment's
notice. To do this a test-tube one third filled with equal parts
of salol and antipyrine should be heated over an alcohol lamp;
fusion is produced in two or three minutes, and a slightly
brownish liquid is obtained, which, however, has the disad-
vantagge of rapidly becoming solidified when withdrawn from
the action of heat for a few moments, and in order to retard
solidification the tube should be subjected to heat until the
mixture becomes of a distinctly brown color; the product thus
obtained will remain liquid for a sufficient length of time.

To introduce this liquid into the uterine cavity a slender
flexible rod is employed, at the extremity of which is a small
tampon of absorbent cotton saturated with the liquid, which
has been brought to the proper temperature for the uterus,
and this is introduced into the uterine cavity without too much
pressure, and the entire cavity painted. Two or three succes-
sive applications are made according to the gravity of the hemor-
ragh: then a tampon of cotton saturated with glycyrin and
cresol is left in the vagina, and the patient is advised to re-
main in bed.

These applications, says the author, are not at all painful and
have never provoked the least accident. Immediately after the
paintings the hemorrhage is arrested, the patient scarcely
losing more than a few drops of blood during the day, and the
day after there is no trace of hemorrhage. It is rare, also, to
have to make another application after the first day.

The Proper Care of Artificial Eyes.—In the Presse médici-
rale for March 2d M. A. Trousson publishes an article on this
subject in which he says that the proper conditions under which
a person may wear an artificial eye relate to the condition of
the cavity and the quality of the eye. The cavity should be
healthy, smooth, free from all adhesions or fungosities, and
containing a stump of sufficient size and having perfect mobility.
The artificial eye should be polished, clear, and exempt from all
roughness, with smooth, rounded edges. It should correspond
to the size of the cavity, and should not prevent the closing
of the eyelids. It should always be in a proper aseptic condition,
so as not to become an agent of irritation or of infection for the
conjunctiva.

Accidents are due, the greater part of the time, says the au-
thor, to the operator limiting himself to enucleation and the
curing of the wound, and then allowing the patient to go to an
optician without further advice. Having allowed him to wear
an artificial eye, beginning three or four weeks after the opera-
tion, when the cavity is no longer irritated and contains no secretion, the physician should show the patient the proper care against further annoyance.

The eye should never be worn for twenty-four consecutive hours, but should be removed every night and placed in a bowl containing a four-per-cent. tdp solution of boracic acid after having been carefully wiped off with sterilized absorbent cotton. If it is put into cold a solution, it will crack and even break in two. In the morning it should not be replaced in the cavity unless it is in a perfectly aseptic condition and free from all roughness, and the hands must be absolutely clean while handling the eye. If it becomes warm and rough, a new one should be used, for any irregularities cause irritation and render cleansing less easy. It is well, says M. Trouseau, to have another eye in reserve in a sterilized bottle wrapped in layers of cotton, also sterilized. On an average, the same eye cannot be worn for more than from four to six months consecutively.

The patient should learn to take out and put in the eye himself; to put it in, the upper eyelid is raised and the large extremity of the eye is introduced under the eyelid and adjusted in such a manner that the long axis is horizontal; then the lower eyelid is pulled down so that the edge of the will finally settle in the cul-de-sac. To remove the eye, the lower eyelid must be pulled down and turned over, and the head of a pin, or a little hook made for the purpose, inserted under the eye, which immediately loosens it, and the eye falls out easily.

The cavity should be washed out every night and morning with a tepid solution of boracic acid, which should be allowed to remain in contact with the spot for a few minutes. The patient can do this easily by throwing his head back.

If the conjunctiva is irritated or painful, the eye must not be worn until all trace of irritation has disappeared, and during this time the applications of boracic-acid water should be continued. The cavity, also, must be protected with a tampon of sterilized gauze covered with absorbent cotton and held in place with a bandage. If there is a moderate secretion in the cavity, the same precautions must be taken and the boracic-acid applications replaced by those of a solution of corrosive sublimate in the proportion of one in four thousand. If the secretions of abundant, it may be well to cauterize the entire surface with a two-per-cent. solution of nitrate of silver. This should be repeated every day or two, according to the abundance of the secretion, and continued until the mucous membrane is dry.

If there are adhesions, surgical interference may be resorted to, and if they are considerable, the cavity should be closed by suturing the eyelids. If there are exuberant granulations in the cavity, they should be destroyed directly with nitrate of silver or with the thermo-cathet.

The Treatment of Boils with Colchicum.—In the Lyon médical for March 3d there is an abstract of an article from the Journal de médecine et de chirurgie pratiques for February 10th, in which M. Brocq says that he has observed that among gouty persons who are attacked with successive crops of boils, but who have neither diabetes nor albuminuria, the extract of colchicum in quantities of from half a grain to two thirds of a grain a day gives favorable and sometimes surprising results, as the following case will show: The patient, a man forty years old, was gouty and for several months had suffered from boils, against which all treatment, whether external or internal, had failed. M. Brocq administered in this case from a third of a grain to half a grain of the extract of colchicum daily, and the effect was surprising. From the fifth day the growth of the furuncles was arrested and no new ones appeared. Fifteen days later the use of the extract was stopped and the furuncles returned. The colchicum was again given to the patient, and the affection was rapidly checked. These experiments were repeated at different times until the patient, perfectly satisfied of the power of colchicum, made up his mind to continue its use for a sufficient length of time, and then gradually give it up. He is now completely cured. As a local treatment M. Brocq advises daily applications of a strong tincture of camphor; the furuncles, also, should be covered with pieces of Vidal's red plaster.

The Treatment of Penetrating Wounds of the Lung.—In the Gazette hebdomadaire de médecine et de chirurgie for March 2d there is an abstract of an article by M. Huguet and M. Ferriere on this subject which appeared in the Revue de chirurgie for 1885. This article, says the writer, is based on three personal observations and leads to the following conclusions: 1. The absolute necessity of treating the wounded person on the spot; the serious consequences resulting from the rolling of the conveyance, no matter how short the distance, render immediate treatment imperative. If the patient has not been driven some distance, the rolling of the carriage will cause hemoptysis, which may cause death in a short time. 2. The condition of syncope, favoring hemostasis, should, within reasonable limits, not be interfered with. Subcutaneous injections of other must, therefore, be used but sparingly unless there is too much depression. In these cases caffeine is especially indicated, and injections of artificial serum should be resorted to. 3. The treatment of wounds of the lung by ordinary means must be, in many cases, insufficient if the wounded person is not subjected at once to an immobility as absolute as possible, which, in itself, says the author, may assure success. 4. The treatment by absolute immobility and immobilization of the thorax does not exclude other procedures when they can be affected without interfering with the patient's immobility. 5. Generally, in cases of hematothorax following a lesion of the large blood-vessels, the treatment should not be active. The symptoms, and especially the complications, must guide the physician in coming to a determination; thoracentesis should not be practiced unless the effusion becomes too considerable and symptoms of dyspnea become serious. 6. The practice of carefully cleansing the patient as soon as the wound has been dressed is to be avoided in every case of penetrating wound of the chest; we should content ourselves with what is strictly necessary, to the exclusion of every occasion of shock.

An Antitoxine for Syphilis.—Surgeon J. Duncan Menzies, of the British Navy, writes to the British Medical Journal for March 2d that the satisfactory results of the antitoxine treatment of diphteria encourage one to hope for a still more brilliant advance in scientific medicine. He refers to the possibility of obtaining a seropathic antitoxine for syphilis. The horse, he says, is known to be subject to a constitutional affection having a marked likeness to the human disease, without, perhaps, a real identity. Again, human syphilis, he says, is incapable of being transmitted to the equine genus. Can we regard this last fact, he asks, as showing a species of antagonism between the two diseases? The bacteriologic of equine vascular disease has not as yet, he believes, been worked out. It would be instructive, he thinks, to compare and endeavor to form an estimate of the bacteriological strength and antagonism of the two viruses, if possible. This discovery, he says, if properly substantiated, might lead to the perfected therapeutic syphilitic.

Brief Local Anaesthesia, says the Practitioner, can be produced by spraying with a mixture of half a drachm of menthol, five drachms of chloroform, and an ounce of ether. The anaesthesia lasts for about five minutes.
ULCERS OF THE CORNEA.

By H. Davison SchwarzSchild, B. L., M. D.,
CONSULTING OPHTHALMIC AND AURAL SURGEON TO THE NEW YORK HOPITAL; ATTENDING SURGEON TO THE NEW YORK POST-GRADUATE HOSPITAL, ETC.

Ulcers are solutions of continuity produced by internal or external agencies. Their origin lies in a superficially disposed infiltration; the surrounding tissue is cloudy, the overlying epithelial cells desquamate, the diseased portion of the cornea breaks down, and an excavation is formed. This description represents the inception of a corneal ulcer. In addition to the disintegration of the most necrotic area, the cloudiness before mentioned frequently increases, accompanied by advancing tissue destruction. The latter may penetrate deeply, proceed superficially in one or all directions, or may assume a serpiginous character. In the first or progressive stage the boundaries are infiltrated and present a grayish appearance, the edges are jagged, and the base uneven. Assuming a typical case, the exudation is cast off and the neighboring infiltration is absorbed, producing a clean ulcer. The cavity is now larger, but on the other hand it is transparent.

This describes the second or regressive stage of an extremely favorable and, generally speaking, of an asthenic case. In the third stage, that of cicatrization, the cavity becomes filled with a reparative exudation. Blood-vessels visible to the naked eye may course from the limbus to the ulcer; sometimes these capillaries are so small as to be invisible without the assistance of a magnifying lens; again, they may be absent, and healing takes place through the agency of the lymphatic channels. The newly formed tissue is cicatricial in character; healing is complete when the cavity is filled and the epithelium restored. In clean ulcers it is occasionally observed that the cellular covering dips down into the excavation, so that the normal reflex is obtainable; the cavity then fills up under the epithelium. This somewhat rare condition must be borne in mind. Rather often the ulcer does not completely refill, the cells cover this tissue in status quo, and a facet results; conversely, in other cases the cicatrix protrudes beyond the surface of the cornea. This is due to the intra-ocular pressure against the thinned cornea, producing a keratectasia. Before discussing the untoward results of corneal ulcers, let us consider briefly the histology of inflammation and repARATION. Cohnheim advanced the view that the motile cells of Recklinghausen, which are in reality leucocytes, produce the inflammatory phenomena; others, Stricker in particular, maintained that the fixed corneal corpuscles were the agents. I am personally of the opinion that the former process is correct. In regard to the repairation of the ulcerative process, the epithelium is formed from that surrounding the excavation, and the connective-tissue growth is an exudation metamorphosis. We are therefore forced to the conclusion that the white blood-cells in physiological proportions are, ceteris paribus, necessary adjuvants to healing, while in excessive numbers they become inflammatory factors. The clearing of corneal cicatrices takes place in the following manner: Through some form of metabolism the new connective tissue disappears and the corneal substance replaces it. The membrane of Bowman is never restored; its absence per se does not interfere in any manner whatsoever with vision. The return of the corneal stroma is effected by a caryocinesis of the stellate fixed cells, with their subsequent development. In this manner, in my opinion, do both corneal constituents engage in repARATION, while but one produces inflammation. As a result of increasing necrosis, perforation is likely to occur; this casualty may be induced by some violent action on the part of the patient, such as sneezing, coughing, etc. Should the perforation be small and be situated over the iris, the latter will become attached to the posterior part of the opening and incorporate itself in the cicatrix (syncchia anterior). If the opening be larger, the iris will protrude and form a cystoid mass (hernia iridis), which by the contraction of the cicatrix will flatten and become denser. A pinhead protrusion is called myiocephalon (Fliegenkopf). In several forms there may occur a total prolapse of the iris. These hernial conditions produce cistic cicatrices and give rise to staphylomata.

Small herniae recently formed possess the normal iris color; later they present a grayish appearance on account of exudation. When the iris has been rarefied through tension, the retinal pigment causes the prolapse to appear black. Should the pathological opening be situated over the pupil, the iris can not be included; hence the anterior chamber becomes obliterated and the lens lies at the site of the perforation. There is a tendency for the same to close by a new tissue formation which emanates from the edges of the wound. It sometimes happens that this thin membranous growth is ruptured by carelessness on the part of the patient or through internal pressure, and a permanent fistula results; the cornea then flattens, the globe becomes soft, and the eye is lost from a general disintegration; conversely, it may temporarily close. The lens, from being in contact with the perforation, may, and often does, develop a capsular cataract. Increased tension manifests itself and ruptures the newly formed plug. This alternating condition may persist for some length of time until panophthalmitis supervenes, and is followed by phthisis bulbii. Perforation may be preceded by a hernia of Descemet's membrane (keratocele), which becomes incorporated in the cicatrix, and, as a clear vesicle, is seen projecting above the surface of the cornea surrounded by white scar tissue. Keratocele may also occur independently, however. Among the fortuities dependent upon perforation, I may mention subluxation of the lens and also intra-ocular hemorrhage. In the former case the passage of the crystalline to the anterior part of the aqueous chamber stretches the zonula and some of the fibers may be levered. Should the corneal fenestration be sufficiently large, the lens may be expelled. Hemorrhage occurs in cases in which perforation takes place suddenly, and where increased tension has previously existed. The sudden removal of pressure permits an increased quantum of blood to enter
the vessels, producing rupture of the same. A vascular degeneration has usually pre-existed; both these conditions are regularly present in glaucomatous and staphylomatous eyes. The hemorrhage may extrude the ocular contents, and likewise may be so profuse as to imperil the life of the patient.

Concomitant Lesions.—From the beginning of a keratitis, circumcorneal injection is manifest. If the ciliary body is moderately affected, there is seen a pinkish circumcorneal halo. With iritis the congestion is much darker and more intense; very often a marked conjunctival injection coexists. In very severe forms of ulcer there is visible chemosis of the conjunctiva, and even edema of the lids. A symptom which has frequently attracted my attention—viz., a dilated pupil and a deep anterior chamber, with but slight inflammatory symptoms and no deposits upon Descemet's endothelium—is a very constant complication of ulcer. The subjective symptoms in mild cases are referable to the corneal lesion; in severer forms there is great pain. I have termed this condition simple serous cyclitis. The tension generally is slightly increased. When iritis is present, in addition to the vascular congestion before mentioned, the pupil is irregular and contracted, the iris dull, often swollen and discolored, and, after a variable period of duration, capsular adhesions are formed. The cornea also becomes hazy and the aqueous turbid.

It is a matter of certainty, established by microscopical examination, that in iritis the ciliary body is likewise involved; but, when the changes in the latter are very slight, they become masked by the iritis. Iridocyclitis is said to exist when, in addition to the iris symptoms, the following are present:

1. Ciliary tenderness.
2. Opacities on the posterior surface of the cornea, and deepening of the filtration angle; the latter, when associated with an immobile pupil, indicates the existence of total posterior synechia.
3. Heightened inflammatory symptoms, with edema of the upper lid.
4. Great disturbance in vision due to opacities in the vitreous. Tension either plus or minus. (The limitation of space prevents my discussing this part of the subject in extenso.)

Hyopyon frequently complicates ulcer; it is derived at times from the cornea, though more often it is of uveal origin; on the other hand, however, it may arise from both sources. The exudation consists principally of pus-cells and fibrinous plastic material. Microscopically, a line is sometimes seen coursing from the corneal suppuration to the anterior chamber. In the pus, uveal pigment is nearly always found, establishing in these instances its intra-ocular origin. The exudation may be fluid or thick; in the latter state it organizes, and may occlude the pupil. In favorable cases it escapes through the ligamentum pectinatum and the lymph channels. It is a regular accompaniment of uvea septicum or its prototype, abscess of the cornea, and occurs without the existence of supplicative keratitis in many cases of iridocyclitis. The quantity of pus varies; it may be almost imperceptible, or, on the other hand, may fill the anterior chamber.

The following data will enable a correct diagnosis to be made through a facile means of distinction: If the corneal surface is dull without a loss of substance, there is present either an infiltration or an abscess; with a demurrage it is a progressive ulcer. If the surface is glistening and the reflex similar to the surrounding normal cornea, we are regarding an old cicatrix. If there is a loss of tissue without the normal reflex, there is a clean ulcer. If the mirrorlike reflex is present, we observe a healed corneal facet, or an ulcer filling under the epithelium. For corroborative, fluorescein may be employed; a few drops of an alkaline solution will produce a play of colors varying from Nile green to canary yellow. A denuded spot will be pigmented by the fluid; the flow of tears or an application of water will remove this subsequently.

Ulcers are divisible into two great classes—primary and secondary. The former arise in the healthy cornea, and the latter are caused by an inflammation of some neighboring membrane. The vast majority of primary ulcers are traumatic in character, accepting it in a wide sense. Inverted isolated cilia, trichiasis, entropion, growths on the free border of the lid, calcareous deposits on the conjunctiva, particles of dust in the cul-de-sac, eczema of the lid, are all extraneous causes. Malnutrition, with consequent hematic changes, frequently acts as an exciting factor. Introduction of bacteria from the mouth constitutes an important causative element. This is particularly true of dispersive patients, in whose oral cavities the bacteria of pyorrhea alveolaris and curious teeth find excellent culture media.

Of the secondary ulcers, we find that phlyctenular, lacrimal, muco-purulent, diphtheritic, and gonorrhoeal conjunctivitis, and trachoma are the great excitants. Suppurative keratitis complicates the exanthemata, and is a direct result of conjunctival inflammation. A corneal abscess, opening anteriorly, constitutes a variety of ulcer. In regard to the causes of suppuration we seek an explanation in bacteria. The principal bacterium of localized pus formation is the staphylococcus, of which there are several distinct forms, among others the pyogenes aureus, citreus, albus, flavus, cereus, etc. In every conjunctivitis we find staphylococci; the virulence of the same depends upon their number and also upon the nutritive fields. With the slightest demudation of the corneal epithelium, these bacteria enter and produce suppuration. Bacilli, after perforating wounds from steel blades, etc., and various forms of fungi—such as the Aspergillus glaucus, after an injury by a beard of oats, and an undetermined species of hyphomycolae following a traumatism by a pear—have been discovered in a suppurring cornea. As a result of my own investigations, I have found that the Spirocheta denticola and the Leptothrix bacillus have likewise produced purulent keratitis and sequelae. In the vast majority of cases the staphylococcus is the only bacterium in evidence. The working classes and old people in general suffer to a great extent from dacrocystitis, with its accompanying conjunctivitis, and also with non-lacrimal conjunctival catarrhal inflammations. Thus a cinder or a
particle of dust which may lodge on, or rather in, the cornea, permits bacteria in this class of cases to enter, and subsequently an ulcer is formed. These foreign bodies may cause only momentary inconvenience, as a sudden flow of tears will suffice to remove them, if very superficial, and immediately afterward the occurrence is forgotten. Thus we can explain the genesis of many so-called idiopathic ulcers.

During the past three years my attention has been particularly called to certain ulcers which occurred in adults where there had been no antecedent conjunctivitis and no traumaism, as far as the patients—who in this particular citation happened to be more intelligent than the average—could recall. From careful interrogation I obtained the information that they used the Harlem and East Rivers as places for nutation, and it at once became evident to me that the raison d’être of the infection had been explained. This method of inoculation is not so very uncommon, and when we consider the morphology of sewage excreta, it need not create the least astonishment.

Of the bacteriology of autogenous ulcers—those dependent upon haemic changes—an analogy can well be drawn between them and acne pustules. Bacteria are to be found in the vascular system, but are innocuous when there are a sufficient number of leucocytes. When phagoctosis can no longer be brought to bear, the pyogenic bacteria manifest their potency by producing suppuration, and the cornea suffers as well as other tissues. In regard to the gross pathology of ulcers, phytycena of the cornea or phlyctenular keratitis, with their evolution, demand special study. These elevations average from the size of a pin-head to a millet seed; they are usually of a grayish color, and may be situated on any part of the cornea, but are usually more or less marginal. They are solid bodies and consist of an aggregation of lymphoid cells between Bowman’s membrane and the epithelium; the smaller ones are completely absorbed at the end of two or three days. The larger disintegrate in the following manner: A minute demudation appears at the apex of the phtytcnula; this continues to increase until the corneal surface is reached; the epithelium may now become restored without a macula resulting, or the process may continue and an ulcer be formed. It is frequently not until this stage is reached that we see the patient.

I described at the beginning of this essay the course of a typical ulcer. As usually seen, however, the picture is different; the stage of progression continues, were we to neglect treatment, until the cornea perforates or sloughs entirely away.

The reparative process is partly indicated by the extension of blood-vessels from the limbus; these are most often found in the superior layers of the epithelium (but may be deeper), their outlet being the ulcer; this heals on one side and advances serpiginously; the vessels continue their progress until in many cases, particularly where there have been several efflorescences, the cornea is covered by this vascular formation. After a cure has been effected they become depleted, but their sheaths can always be seen as faint striae. This is the so-called vascular fasciculus.

Herpes cornæ (febrilis, or zoster) occasions ulcers through the rupture of the vesicles. They spread superficially, but do not penetrate deeply. The tendency is to produce an arborescent figure, to which condition has been applied the term keratitis dendritica.

Ulcus rodens runs a characteristic course. It commences near the margin of the cornea, usually on the superior border; the edges are undermined and heavily infiltrated; the inflammatory symptoms are well marked. The ulcer subsequently cleanses itself, vessels form, and cicatrization commences. Suddenly a relapse occurs, the ulcer extends with a recurrence of symptoms, and ultimately the entire cornea has become cicatrical. This disease occurs principally in adults, and frequently involves both corneas, either simultaneously or successively; perforation is rare. The three forms described have given rise to the designation of serpiginous ulcers. Small marginal ulcerations often occur without ascertainable cause. Ulcers from conjunctivitis are either crescentic or irregularly round; they are usually more or less peripheral. In gonorrheal and diphtheritic conjunctival inflammations ulceration generally commences inferiorly and spreads rapidly, most frequently with the sequel of panophthalmitis.

Traumatism furnishes a large variety of ulcers; some are small and superficial, healing rapidly under favorable conditions, and are uniformly situated in the palpebral fissure. Another form is very malignant: the edges and base of the wound are yellow, and hypopyon is regularly present. Their course is isologous with that of abscess—in fact, they are small superficial pus foci which have opened anteriorly; they have been described by different observers as ulcus serpens, ulcus septicum, and hypopyon keratitis. The process advances rapidly and the deeper structures become affected synchronously. The disease is distinctly sthenic in character, and the tendency to perforate is marked. From the appearance and rapid growth of the lesion one would assume a more malignant bacterium to be in evidence; but, as culture tests refute this view, we must conclude that the virulence of the staphylocoecas depends largely upon the soil. An abscess of the cornea is not circumscribed; it is diffuse on account of the arrangement of the corneal stroma, in the interstices of which the pus is to be found. The name onyx has been given to an interlamellar pus focus.

A very destructive genus is the “ring ulcer.” This consists of a parululent groove surrounding the cornea, with the involvement of the adjacent structures. It often follows a ciliary wound, but may occur without a definite history of traumatism. The condition is absolutely incurable. In glaucomatous and staphylomatous eyes ulcers distinguished by their rapid progress and incurability are seen to occur. The eyes are generally lost through extension of the inflammation. Knowing that the underlying cause is an ocular degeneration, the unfortunate prognosis is readily understood. Old corneal cicatrices frequently necrose, giving rise to the so-called atheromatous ulcers; they possess a tendency to recur, and may also perforate. In trachomatous pannus small ulcers arise, which may penetrate deeply or coalesce and form one large crescentic cavity. Besides
the many characteristic forms which I have described, excavations occur which vary in size from a needle point to a lentil, the etiology of which is often very obscure.

In regard to the general symptomatology of ulcer, a variable trio is present—pain, photophobia, and lacrimation. The first is local, referable to the distribution of the superior maxillary division of the trigeminal nerve, or may be entirely absent.

Photophobia is in certain cases intense; this bears with greatest emphasis on the phlyctenular keratitis of children; in the central ulcer of trachoma we note the opposite extreme. Lacrimation, in my opinion a most favorable symptom, as it keeps the pathological cavity bathed by the antiseptic tears, is present to a greater or lesser degree in every instance. These symptoms are not by any means in proportion to the size or severity of the lesion. I have observed the greatest amount of irritation produced by a superficial denudation exposing the subepithelial nerves arising from a child’s finger nail abrading the cornea.

When iritis intervenes, the pain, particularly nocturnal, is very severe. Cyclitis, when it occasions increased tension, is also accompanied by pain varying in intensity. Hypopyon should not be confounded with abscess, and when both are present lateral examination of the cornea and anterior chamber should prevent any error from occurring.

The duration of an ulcer depends largely upon the therapeutic measures employed. The object of treatment is to refill the cavity as soon as possible. Local medicinal treatment aims at causing death of the bacteria; it is supposed that the ulcer will then cleanse itself and subsequently heal. Logically and theoretically this is perfectly correct; practically it is the reverse. The treatment, which has been in vogue for a long period of time, consists in applying antiseptics locally; boric acid, iodoform, quinine, pyoecin, yellow-oxide ointment, aristol, etc.—have all been used. I can not say much in their favor; those which possess any efficacy whatever are either mechanical or chemical irritants, and the non-irritating ones are absolutely useless. In regard to the former, conjunctivitis with its accompanying microbes is the result of their employment, and the ulcer is thereby exposed to reinfection. An ulcer will in time either heal or perforate, and these medicinal agents have less influence on the reparative process than in facilitating the progress of ulceration. No doubt there are a few cases in which colonel, etc., have apparently improved the existing conditions. There is not the slightest doubt, however, but that Nature affected the cure despite the medicine.

The treatment par excellence is cauterization; for this purpose we employ the actual cautery, preferably by a platinum probe heated in an alcohol flame, or a saturated solution of carbolic acid by means of a rounded match, using cocaine as a local anesthetic. In either case light contact only is required, and one application usually suffices. The eye should first be laved with a weak solution of creolin or phenol; boric acid \textit{ad saturandam} may be substituted. Carbolic acid is applicable, in my opinion, only in large ulcers; whenever practicable I prefer the actual cautery. The former produces good results, but the surrounding cornea may become hazy for a day or two. Neither nitrate of silver nor bichloride of mercury should ever be applied directly to an ulcerative surface, as metallic deposits may result. (In conjunctivitis when ulcers develop the silver may be discarded, and in exceptional cases, if it is imperatively required, the corneal lesion should be covered by the palpebral conjunctiva and thus protected). Notwithstanding the fact that certain writers hold diametrically opposed views on the subject of silver, my opinion is unalterable. Acetate of lead is a dead letter in modern ophthalmology, and in a well regulated practice is rarely if ever employed. It does not possess any advantage over the other commonly used agents, and its application is attended with the danger of precipitation. Should there exist any corneal denudation whatsoever, a lead incrustation will invariably take place, which must subsequently be removed surgically.

Curettage has been brought into prominence. The ulcer is cleansed, it is true, but it is in the state in which infection may be introduced, and, secondly, the stimulus to healing is absent. Considerable irritation follows this procedure. When we observe a regressive ulcer our desire is to promote reparation; for this purpose heat, either by means of hot compresses or with a vaporizer, is called into requisition; in the majority of cases it is to the cautery that a final successful appeal is made. It is therefore much more reasonable to employ the efficacious method first and at all times. Phlyctenulae of the conjunctiva and scleral-corneal junction should be cauterized; it is the cleanest and most satisfactory mode of treatment, and if a nebula result therefrom it is of no moment. When on the cornea, their absorption may be hastened and facilitated by heat or gentle massage, a small amount of bichloride vaseline being placed in the \textit{cul-de-sac}. When through progressive ulceration the elevation has been destroyed and a corneal excavation of varying size is produced thereby, the appropriate treatment for this condition is required. Every corneal denudation which has destroyed any part of the substantia propria will leave a nebula; cauterization will not enlarge its size. By my emphatic advocacy of this method it must not be assumed that I burn every ulcer; on the contrary, I discriminate most carefully, and thereby exclude about ten cases out of a hundred. Those which are not operated on at first sight are clean, non-infiltrated ones, also aseptic ulcers, epithelial desquamations, recent abrasions, and non infective traumatisms; the latter I judge of by the appearance rather than from the history. The only exception to the foregoing statement is the following: In the event of a foreign body being imbedded in the corneal tissue and surrounded by a zone of infiltration, in this case it suffices to remove the \textit{corpus delicti} and scrape away the detritus. Subsequently if the ulcer does not heal in a satisfactory manner it may become necessary finally to cauterize.

The employment of only mild and conservative treatment in progressive and progressing ulcers is, in my opinion, extremely ill-advised. I do not condemn mild treatment at the start, but when its inefficiency is demonstrated at the expense of the patient’s eyes, I consider that the appropriate measures are imperatively demanded. In order that the best results may be obtained from the cautery, the
employment of a mydriatic or the combined use of mydriatic and myotic, in a large percentage of cases, becomes indispensable. In regard to the use of atropine, be the pupil large or small, it should first be artificially dilated. When evidences of simple serous cyclitis are present (deepened anterior chamber and a dilated pupil) after the primary instillation of atropine, the myotic may be used. For this alternation the following axiom may prove of service: as much eserine as possible—avoiding the causation of an iritis—and as little atropine as possible, sufficient only to maintain a mobile pupil. Generally speaking, this resolves itself in many cases thus: Assuming that we see the patient during the morning, one drop of atropine (one half per cent. for very young children, for others one per cent.) once; one drop of eserine (one fifth per cent.) noon and evening. Second day—morning atropine, and eserine at midday, evening atropine. Third day—morning atropine, and eserine not to be used that day.

On the fourth day, if there are any objective symptoms of cyclitis, the alternation should be resumed, beginning as on the first day, and be continued until the inflammatory signs dependent upon ciliary involvement are on the wane. It is impossible to accurately lay down the law in this matter of alternation, as the eyes of different persons differ in regard to reaction, and it is only through experience that these agents may be employed with advantage and without danger. The rule described above will, however, be of assistance to those unfamiliar with this practice. The main thing is to observe whether the pupil shows an inclination to respond to light; if it remain contracted and irrespective eight hours after the employment of the eserine, there is present a most positive indication that iritis is intervening, and atropine is demanded post-haste. It would show a marked appreciation of the warning if the myotic were now consigned to the shelf for a few days, and then used very cautiously. A few experiences of this kind will render the general practitioner quite expert. I have seen the above-mentioned accident occur in given cases when the attending physician, through lack of experience with this class of diseases, failed to recognize the importance of carefully regarding the mobility of the pupil. By exercising a requisite amount of skill and care this casualty can invariably be avoided. In order to alternate with safety, it is necessary—absolutely so—to see the patient every day. In private practice, twice, and even thrice daily reduce ad minimum all fear of intercurrent complications and naturally improve the prognosis ad optimum. With this treatment it is not a question of the end justifying the means; on the contrary, although there are dangers attendant upon its use in the hands of an inexperienced and untrained person, it is as nearly infallible as anything can be. Any sthenic ulcer treated otherwise than by the cautery, and, if cyclitis coexists, by the eserine atropine alternation combined therewith, is mismanaged. Be there neither iritis nor cyclitis, atropine in moderation is requisite, not alone for its benign influence on the cornea, but as a prophylactic to prevent the intervention of iris congestion and inflammation. Any person desirous of conscientiously and successfully ministering to these cases should familiarize him-
SCHWARZSCHILD: ULCERS OF THE CORNEA.

[N. Y. Med. Jour.,

are applicable only in exceptionally severe cases. Under all circumstances the conjunctiva and the fornices must be carefully irrigated and disinfected several times daily by means of a glass eye-douche (undine) filled with any mild non precipitating antiseptic. The surgical rule of causal treatment bears with great emphasis upon this class of diseases. Galezowski and Bourgeois lay stress on the causative relation of lacrimal catarrh in the production of severe autogenous ulcers.

Constitutional medication is imperatively demanded. Besides improving the hygiene and mode of life, a medicinal food—viz., cod-liver oil, preferably emulsified and combined with quinine, strychnine, hypophosphites of calcium, sodium, iron, etc.—should be administered during the cooler months of the year.

Alternatives—such as arsenic, the syrup of the iodide of iron, citrate of iron and quinine, calomel, and bichloride of mercury in small doses—are likewise indicated.

In old trachoma cases the external canthus is tightened, and the roughened conjunctiva irritates the cornea; a canthotomy or canthoplastic relieves the condition. The former procedure is also applicable in the blepharospasm of children, who suffer so intensely from photophobia in the various forms of keratitis. Trachoma should be treated by any rational method.

In phlyctenular keratitis there is almost invariably an associated dermatitis of the lids and the contiguous integument of the cheeks; there is also an inflammation of the nasal mucous membrane, and the acrid discharge produces exoriation at the orifice of the nostrils, the angles of the mouth, and at whatever site it may reach.

In addition to the ocular treatment, the nose should be kept clean; a solution of sodium chloride (\(\frac{3}{4}\) j to \(\frac{7}{8}\) viij) is to be poured into the nostrils with a medicore dropper three times a day. For the eczema the ointment of the yellow oxide of mercury (gr. iv to 3 iv) may be advantageously used.

If an ordinary ulcer without iritis be seen within three days of its inception, the treatment by the cautery, combined with the mydriatic-miotic alternation, effects a cure in five days—at the utmost seven. The longer an ulcer has existed, the less amenable does it become to treatment.

The imminence of perforation renders the prognosis more serious; nevertheless, I have repeatedly had cases in private practice, in the babies’ wards of the Post-graduate Hospital and elsewhere in clinics, in which neglected or badly treated ulceration had exposed Descemet’s membrane, and others in which keratocele had been occasioned, and, through the cautious use of the cautery and combined treatment, perforation was avoided and healing resulted. There exists a marked correlation between the mobility of the iris and the activity of the corneal circulation; so that, when an iritis is present, we can not expect such rapid reparation, and vice versa.

The bandage plays an important rôle in the treatment of the disease under consideration; there are two varieties, the protective and the pressure. Let us consider the former. During the periods that applications are not being made, a large, soft handkerchief may be tied diagonally over the head, covering the eye, a layer of cotton being interposed. A muco-purulent discharge, unless great cleanliness prevails, constitutes a deterrent. At all events, the patient must not become too accustomed to the eye remaining closed. As soon as the ulcer is healed, a pair of smoked glasses should be substituted, and these will afford sufficient protection from the sun’s rays, etc. Generally speaking, the bandage is of most value when patients are exposed to the elements, etc.; this applies with particular force to the poorer classes. For private patients a dark cloth pad suffices. The room should neither be kept dark nor, on the other hand, extremely light. As children have a tendency to rub their eyes whenever there is any irritation, traumatism may be prevented by wearing a wire protector. The same is true to a lesser degree of adults, particularly at night; an accidental rub may effect considerable and even irreparable damage. I have devised an appliance for this purpose which consists of a ventilated concavo-convex mask made of wire, closely interwoven, resembling somewhat a hair sieve in appearance. There are two sizes, large and small, for adults and children respectively. When photophobia exists, the protector may be lined with any dark material. The former may also be placed over a bandage in cases of thinned cornea; the advantage is manifest.

The pressure bandage is made by applying several layers of gossypium to the closed eyelids and covering this with the roller. The compression is dependent upon the amount of interposed cotton and also upon the firmness with which the bandage is tied; the indications will be considered later.

The treatment of hypopyon does not materially differ from that of the other forms, except that there the pus and the iritis must be considered. The ulcer should be managed secundum artem. The purulent exudation, if scanty, may be absorbed either by the application of heat or the internal administration of sulphide of calcium. In the event of its being larger, or persisting, though small, an infero-corneal incision should be made; if tenacious, the hypopyon may be withdrawn with an iris forceps; if fluid, it escapes of its own accord. Should the ulcer extend, notwithstanding the catarization, on account of increased tension, with or without the continuation of the hypopyon, we must proceed à la Saemisch. This procedure is as follows: Make the puncture and counter-puncture in clear cornea with a narrow-bladed knife, bisecting the ulcer. The anterior chamber may now be freed from the pus. The iris will become adherent to the cornea and healing is likely to result. In treating this disease we must bear in mind the implication of the ciliary body, as well as that of the iris. The prognosis is always more or less grave.

In regard to sequelae, in general, when perforation is about to occur, be it preceded by a keratocele or not, absolute rest is necessary and a mild pressure bandage should be applied. The intra-ocular tension, if increased, may be diminished by the meiotic mydriatic “seesaw.” Paraentesis is also applicable, but in the attempt to pierce the cornea the latter rarefied membrane may rupture. For the relief of intense pain, even with the attendant risk, it is preferable to make a sclero-corneal puncture in healthy
tissue rather than follow the procedure adopted by some operators—viz., to needle the ulcer and evacuate the aqueous. If perforation be inevitable, assistance of that character is not required; and if it can possibly be avoided, our duty is to produce healing in as natural a manner as possible, which does not mean incorporating the iris. Should the tension be diminished, atropine alone avails us. The ulcer should at all events be cauterized, and in my practice, as I mentioned before, I have observed cases in which perforation seemed on the point of occurring every moment, and this untoward result was staved off and the ulcer subsequently healed. Should a keratocele be situated over the iris it may be punctured with good results. I personally prefer to induce healing and incorporate the vesicle rather than produce a synchia anterior. When perforation has taken place the aim must be to create a firm cicatrix. Very small herniae do not prolapse; larger ones do. If the iris inclines toward the formation of a cystoid mass, it may be cut off on the flat, or according to Leber's method. Adhesions to the cornea may be separated, the contiguous portion off the iris drawn out and snapped off. A coloboma is occasioned thereby and a fistula is likely to result. In the former procedure the iris, in most instances, will continue to prolapse and to form a cyst, and the cornea will become kerectatic. The choice now remains, shall we apply a pressure bandage and hope, or employ a more drastic procedure with expectations of a successful issue? In these cases iridocyclitis of varying intensity is almost invariably present. If this condition is permitted to persist, the eye will most certainly perish. Should the corneal rarefaction be allowed to progress, the sequelae of staphyloma, Critchett's operation, and enucleation confront us. Even sympathetic ophthalmia from abscession of the staphylomatus cornea, followed by passing sutures through the ciliary body, may be occasioned. Cauterization in most cases produces a firm eschar, assuming that the eye has not entirely disintegrated. Semi-occasionally an enterprising historian reports that the cautery has produced iridocyclitis, forgetting apparently that this condition previously existed. I can readily appreciate the fact that an aggravation of symptoms may be occasioned; it occurs but infrequently, however; at any rate, this procedure is the only efficacious one extant. Patients suffering from fistula of the cornea should rest in bed. The edges of the wound may be lightly touched with the cautery, and when the opening is closing, the intracocular tension should be kept as normal as possible. A pressure bandage is required. These cases are not very encouraging.

In regard to corneal nebulæ and leukomata, it may be stated in general terms that the larger the opacity, notwithstanding its superficiality, the greater the visual impairment. The rapidity with which cleftrices of the cornea are absorbed in childhood is remarkable. After twenty-one years of age the resorption is almost nil. In order to facilitate their disappearance, gentle massage and vaporization may be advantageously employed. Electricity for this purpose is futile and pernicious. Trichectomies for visual purposes are feasible when a sufficiently clear corneal site remains. Upward colobomata and central scars are trophies of an obsolete method of treating ulcers. I have seen quite a number.

The Treatment of Colles's Fracture.*

By NATHAN JACOBSON, M.D.,
Professor of Clinical Surgery, College of Medicine, Syracuse, N.Y.; Surgeon to St. Joseph's Hospital, Syracuse, N.Y.

EIGHTY years ago Abraham Colles described a fracture of the lower end of the radius. To-day we recognize that the injury which bears his name is the most frequent form of fracture. Its treatment has so often resulted unsatisfactorily that it has probably been the occasion of more suits for malpractice than all other forms of fracture combined. It is particularly a subject deserving our earnest consideration.

Rational treatment of an injury rests upon a correct conception of its pathology.

It will be recalled that the deep fascia passing down from the forearm to the wrist is closely connected to the bony structures forming this joint. It is wrapped about the tendons which pass to the hands and fingers, forming resting places for the same. This fascia, secured to both bones and tendons, is spoken of as the annular ligament. Besides this, we have strong ligaments attached laterally on each side. Externally the styloid process of the radius and the scaphoid are secured together, while internally the corresponding process of the ulna is fixed to the cuneiform and pisiform bones. Both of these are intimately attached to the annular ligament. This joint is furthermore protected by an anterior ligament, which is composed of three bands connecting respectively the lower end of the radius, its styloid process and the ulna to the palmar surface of the scaphoid, semilunar, and cuneiform bones. Posteriorly, a ligament less strong secures the lower end of the radius to the three bones of the carpus just mentioned. It will be remembered also that the ulna does not directly articulate with the carpus, but placed between them is the triangular fibro-cartilage, which, attached as it is to both bones of the forearm, serves also as a ligament.

Our most recent text-books still describe this injury as a fracture of the lower end of the radius. The injury to the radius is emphasized. It must be a matter of surprise to the thinking surgeon, if there be merely an uncomplicated fracture of the lower end of the radius, that bad results so frequently follow its treatment. Fractures of a long bone, particularly when superficially placed and guarded by a parallel long bone, do not present ordinarily any obstacles in their care.

But it is evident, upon simply viewing a Colles's fracture, that the deformity is not limited to the radial side of the forearm. Inspecting either the anterior or posterior surface of the wrist, it is at once apparent that there is as much if not more abnormality on the ulnar than on the radial side.

* Read before the Medical Society of the State of New York at its eighty-ninth annual meeting.
At the annual meeting of this society in 1879, Dr. Edward M. Moore, of Rochester, presented the result of his study of a then recent case of Colles's fracture. It has been said that the condition found by him is not one usually existing in Colles's fracture. It occurred in a woman who had thrown herself from a great height and had sustained fatal injuries. Colles's fracture, on the contrary, is the result of a slight injury. Yet no one will pretend to say that in a given fracture the extent of damage produced is in each instance the same.

Experimental study has shown that the position of the ulna is so changed in this "fracture" that it is proper to describe the pathological condition as one of dislocation of the lower end of the ulna associated with fracture of the radius. Dr. Moore found, in the case referred to, the internal lateral ligament stripped from its styloid attachment and the triangular fibro-cartilage torn off. The ulna, freed from its ligamentous restraint, became entangled in the deep fascia known as the annular ligament. To this entanglement rather than the radial fracture he attributed the deformity produced. Dr. Moore also found that the tendon of the extensor carpi ulnaris—which, passing through the annular ligament, is placed normally between the head of the bone and its styloid process—was thrown out of place in such a manner as to favor this entanglement of the ulna in the annular ligament and secure it in this position. In a paper presented ten years later to this society additional evidence was adduced corroborating these views.

Dr. L. S. Pilcher placed before the New York Academy of Medicine, at a meeting held May 16, 1878, the result of his experimental study. He demonstrated that the periosteum was not completely torn off from the posterior surface of the radius, but still remained attached to the upper fragment in such a manner as to secure the lower fragment in its faulty position. Displacement of the lower end of the ulna was in every case apparent. The immobility of the ulna in its abnormal position was, he believed, the result of its fixation by the strong oblique fasciculus of the anterior ligament, to which reference has been made as passing from the inferior extremity of the ulna to the cuneiform bone.

Bardenheuer, in an elaborate article upon injuries to the upper extremities, which appeared in 1888 as part of Billroth and Luecke's Deutsche Chirurgie, describes as occurring in connection with fracture of the lower end of the radius at least six degrees or forms of dislocation.

Tillmanns, in the third edition of his Operative Surgery, just issued in Germany, refers to luxation of the ulna and fracture of its styloid process as complicating fractures of the lower end of the radius. But these did not present the deformity characteristic of Colles's fracture. Where the clinical picture which we recognize as that of Colles's fracture is present, it is evident from what has just been stated that there exists, in addition to the radial fracture, a fixed displacement of the lower end of the ulna.

The questions which now present themselves are, first, How can we return both bones to their normal position? and, second, By what means can they be secured when replaced?

Although not agreeing as to the cause and persistence of the ulnar dislocation, both Moore and Pilcher are agreed that extension combined with pressure upon the fragments of the radius fails to overcome the deformity in Colles's fracture. But by first extending, then carrying the hand to the radial side and bringing it as far backward as possible, the ulna is released from its entanglement. Moore advised, further, to replace the tendon of the extensor carpi ulnaris, that the hand be swung from its backward position to the ulnar side, and completing circumduction by forcing the hand finally into a position of flexion. During this manoeuvre an assistant holds the forearm, and the hand of the patient is grasped by the corresponding hand of the surgeon. While the traction and manipulations are being carried out, the opposite hand of the surgeon is so placed that the thumb presses against the lower end of the ulna, thus forcing this bone upward and into place, and secures at the same time the return of the extensor carpi-ulnaris tendon to its proper position if it be found misplaced.

For the purpose of completely relaxing the ligaments which are responsible for the displacement it is wise to administer an anesthetic. Without it the operation is painful, and the patient unavoidably resists the surgeon, so that reduction is not as easily or satisfactorily accomplished.

That the first step in the treatment of a fracture is its reduction no one will deny. In the treatment of so-called Colles's fracture not only is this emphatically true, but, when once completely reduced, the displacement can not be reproduced by any ordinary movement.

Most surgical works contain themselves with stating that reduction of the fracture can be accomplished by extension combined with direct pressure upon the lower fragment either with or without the aid of an anesthetic. This procedure does not recognize the ulnar complication, and therefore fails to accomplish the desired result. For myself, I have followed the teaching of Dr. Moore, and I must confess that I have not met the serious deformities and the useless hands which have caused so much suffering and litigation.

As opposed to the very meager reference to the method of reduction, our text-books and special works upon fractures and dislocations devote many pages to the question of after-treatment. Exhaustive descriptions of numberless splints recommended by various surgeons, with illustrations of the same, can be found in all of these works.

It is self-evident that no kind of splint or dressing can secure a good result for an unreduced Colles's fracture. Too much emphasis can not be laid upon the fact that the whole secret of success rests with the proper reduction of
the fracture. Once properly reduced, it is a matter of no consequence whether an anterior or posterior splint or both be used, whether the splints be straight or pistol-shaped, whether they be simple in their construction or complicated mechanical contrivances.

I must confess never to have had any experience with any kind of splint. Having reduced the so-called fracture, I have placed, as suggested by Dr. Moore, a single-headed roller bandage, two inches in length and half an inch in diameter, under the ulna from the pisiform bone upward, and secured it in place by an equally broad adhesive strap which encircles the wrist. The forearm is placed in a narrow sling; the hand, in a slightly prone position, overhangs the same, and by its own weight secures the ulna in its normal position. Some swelling follows the first dressing. It is therefore advisable to split the adhesive strap upon its dorsal surface immediately. After a few days no further swelling occurs, and a new dressing can be applied, which remains intact.

As a matter of fact, reduction having been accomplished, Nature has provided us with the best kind of splint. The ulna lying at its side prevents any displacement of the fractured ends of the bone. All that is required is to place and secure this splint in its proper position. The reduction accomplished, the pad and strap, assisted by the position of the hand, secure this end. The patient is given to understand that the sling and pad must remain as placed.

In no other fracture is there such marked tendency to stiffness of the joints and infiltration into the synovial coverings of the tendons. Splints, of whatever character, by their restriction of active and passive movements favor the development of this condition. This has been recognized by surgeons who use splints or fixed dressings, and many of them now advise their daily removal after the second week, to permit passive movements, and their complete removal after twenty days. For myself, I not only permit but advise the patient to move his fingers daily as much as he pleases, and after the first week I institute passive wrist movements. There is no pain during the after-treatment. This freedom from pain I regard as indicative of complete reduction. If pain persists after Colles’s fracture, I believe the reduction is incomplete. After three or at most four weeks, the dressing is removed, and the patient finds himself able to use the injured extremity as before and with complete freedom from stiffness or non-use of the extremity.

The very satisfactory results which have followed this line of treatment make it a matter of great surprise to find one of our recent surgical writers recommending as suitable for the treatment of this injury the fixation of the forearm and hand as far as the metacarpophalangeal articulation in a plaster-of-Paris bandage. This line of treatment is one which has been pursued extensively in Germany and France. It is so entirely opposed to correct surgical principles that we are prepared to learn from a German surgeon that the resulting deformity is often extreme, that ulceration, phlegmon, and gangrene of the soft parts are frequently produced.

Bardenheuer, dissatisfied with the plaster-of-Paris treatment, presents what must seem to us a most remarkable alternative. He advises placing the patient in bed and confining him there during the period of treatment. The hand and forearm are placed upon a support with an upward incline. The hand, projecting beyond this splint, has attached to it an extension apparatus the cord of which is carried under a pulley fixed to the bottom of the footboard of the bed and is brought up over a second pulley at the top of the footboard, and to it the weights are attached. The extension is directed in such a manner as to overcome the existing deformity.

As opposed to these complicated methods of treatment, the simplicity of that necessary after proper reduction is apparent to every one. The only extension required is that secured by the weight of the hand. The only splint necessary is the one Nature furnishes—the ulna. There is no reason for producing immobility of the hand or wrist, which only results in stiffness and non-use. The older methods of treatment, by whatever form of appliance, have served only to bring discredit upon the profession. We are in possession of sufficient knowledge of the pathology and correct views of treatment of this injury to realize that the proper treatment lies in its complete reduction rather than in any form of after-fixation.

AN INTERESTING CASE OF MALINGERING OCCURRING IN PRIVATE PRACTICE.

By HENRY F. PARKER, M.D.,
POCKEVILLE, N. Y.

A number of years have elapsed since the occurrence of the case which I now report for the first time. It is one not remarkable in any particularly medical way, but is interesting as showing how some of the habits can be imbued with the idea that, to become prominent in the medical world, a member of the large family of so-called freaks would be to them of immense value as a capital in trade, being indorsed by physicians, by exhibiting themselves. The scene might be laid in a country village; time, the spring; and the dramatis persons, a father, daughter, some kind friends, consulting physician, and the physician in attendance, who, by the way, has gone to rest since the occurrence of the following facts:

My father, a practicing physician at the time, was called in to see the case by the attending physician, and I, a young man, became very much interested in it, and, as I shall describe later, took a somewhat active part in the drama. The previous history is somewhat of a blank, notes of the same being unattainable. It runs along in the style of the following: The patient, a married woman, named, we will say, Mrs. P., about twenty-two years of age, had one child six years old, and following her birth a number of miscarriages. She was considerably run down in health, and was advised by the attending physician to try a change of climate; consequently she went away to visit a friend in a small country place, which was in a limestone region. While visiting, this friend took considerable interest in her and her doings, and often remarked the exceed-
ingly small amount of blood which she passed at her menstrual period, and also the fact that the amount of urine was decreased.

This, the patient informed me afterward while getting her history, kept on decreasing until some days she hardly passed any urine; and, in fact, went two or three days at a time without doing so. She was advised to return home for treatment of this trouble, and, coming under the care of the *dramatic person* attending physician, he placed her upon diuretics and tonics without any seeming result. Every available means was tried to aid Nature, but still it continued, and she began to lose flesh (so she says), until it was finally determined to have a consultation, and my father was called in. The history he obtained was about as above recorded, except for the fact that she had begun to pass stones of a peculiar character instead of urine, or sometimes mixed with a little urine. Upon the second visit of my father I accompanied him, and what follows is from notes now in my possession and made at the time. Upon reaching the homestead and meeting the attending physician in a room down stairs, we were shown a stone, about three quarters of an inch in width and about the same in breadth, which, excepting one sharp corner, was as smooth as could be. It had the peculiar odor of urine which a renal calculus has, or anything which may have been put into urine and then dried. The treatment at that time, which consisted of diuretics, was still advised to be continued. In passing out to the wagon my father made the remark that it did not seem to be a renal calculus, but had the appearance of an ordinary stone which might be picked up anywhere in that locality, and, in fact, he picked up one which bore a very close resemblance to the one said to have been passed. The physician became quite provoked about this remark, and stated that he knew it was true that she had passed the stone, as he himself had taken it from her. All sorts of suggestions and ideas were offered as to what condition the ureter of the right kidney was in, as it was in that kidney that the trouble seemed to be, the reason for it being given that during the passage of these stones the pain which she underwent was referred to that locality. In order to substantiate his statements, and also because he saw that I was very much interested in this peculiar phenomenon or freak of Nature, the attending physician requested me to help him take charge of the case, which request I gladly accepted, and became from that time one most interested to prove facts if true, and, if not, to show or find cause of this peculiar disease. In fact, I might say that I became a medical detective, and from Sunday, April 10th, to May 20th I met the attending physician in consultation at either morning, noon, or night, so as to see the case in all its peculiar points, besides many times taking full charge of the case, making in that interval of time about thirty visits. During all the first part of this period she was passing small, sharp-pointed stones, which were exceedingly hard in substance. To control the pain she experienced from them she used two hypodermic injections of morphia sulphate, an eighth of a grain each time, during the day. Her appearance was of a fairly well nourished person, and her color, save for a peculiar flush which would start from her neck under her cheeks and gradually flush out, spreading all over her face, so that on pressure it would leave a white mark for a short time and then fade away again, was extremely anaemic. She was passing no urine whatever to speak of, save perhaps a teaspoonful or tablespoonful in the twenty-four hours, and that usually whenever a stone passed her, at which time it was accompanied with a lot of very finely powdered matter, which looked like gritty, sandy soil. The stones, some of which were sent away to be examined, were said to be renal calculi. We were forbidden by her father to break or otherwise destroy any of the stones, as he wished to keep them all intact. Therefore they could not be obtained to be analyzed. Among other remarkable symptoms she had no appetite, and since the passage of her first stone had lost her voice, though what connection that had with her kidneys is hard to conceive. So stood the general state of affairs, with the constant trial of new remedies for her relief without any result.

On May 5th, however, a specimen of her urine was obtained sufficient to make an analysis of. It was the first large quantity she had passed since she came under my notice—altogether about two ounces and a half. For the last three days previous to this she had not passed a single drop, although her bowels were at this time remarkably loose. The result of the analysis was as follows: Specific gravity, 10.94; reaction slightly acid; no albumin; no sugar. Microscopic examination revealed only a few vaginal epithelia, the sediment consisting of earthy phosphates. Her pulse during this period was very variable; on May 6th it was beating as high as 104; although during the period of hot flashes that I have spoken of was not an uncommon pulse rate.

On the morning of May 8th her father called at my office and wanted me to call upon his daughter without the attending doctor knowing about it. During the course of the conversation he requested me to show him some pictures of stones that had been passed from the kidneys, which I did; also showing him some large calculi which had been removed on post-mortem examination, although I did not tell him of the fact. He spoke of the case as one of exceeding great curiosity and interest, to which I agreed, and he made the statement that he thought it would be one of importance to the medical profession at large to see which they would travel many miles. I arranged with him to see the case that afternoon, a little before the time I was to meet the attending physician, and requested him to tell the doctor that was my plan. I reached the house about 3 p.m. and obtained from the patient a corroboration of about all the history I have given. She said that she was still passing stones in great agony, and that they seemed to be growing larger. She described the feeling she experienced when a stone left the kidney as one of a very sharp, acute pain, as it engaged itself in the ureter and started on its downward course. She said she could place her finger upon the spot which the stone occupied in its various halts, which were many, on its downward passage, and at last, when the mouth of the ureter was reached and the stone dropped suddenly into the bladder, she said it produced such a violent shock that it threw her into a convulsion, which lasted a long time, and during which the doctor had to be sent for, often remaining with her all night during the passage of a stone. The pain produced by the stone passing from the bladder through the urethra to the vagina was not so acute. But she had to use a soft-rubber catheter occasionally to push the stone backward a little, or to change its course, when one of the sharp edges became engaged in the wall of the urethra on its downward course. The doctor told me that he had made several examinations, but had only found the neck of the urethra slightly swollen. She then kindly informed me that she had great faith in my treatment, and had also had dreams in which she had been shown that I was to be the rescuer of her life. When nephrotyony was proposed she objected decidedly to it, and said she preferred death. Upon the arrival of the doctor we decided to use the benzoate of sodium which had been suggested by my father, to see if we could produce any result in obtaining hippuric acid. Upon our returning to the patient's bedside I spoke of the change of medicine and what results we desired, describing as nearly as possible the appearance of hippuric acid. The next day she began passing large quantities of a white, solid substance, with a slight increase in the amount of urine. This peculiar white substance was covered with small granular dust and fine gravelly matter, which
to all apparent purposes seemed to indicate the disintegration of the calculi (?). This material was tested and in some ways seemed like hippuric acid, while in others it was not at all; what it could be was a new mystery to all the physicians concerned. The stones were now appearing in a much enlarged size and were accompanied with severer pain and more lasting convulsions. She now complained of a peculiar dripping sensation in the kidney, which she described as consisting of a thick, mucilaginous substance slowly gathering itself together and dropping into a large cavity (probably referring to the pelvis of the kidney), and when a stone started from the kidney the sensation increased. Every stone which was passed from this time on was accompanied with more or less of this peculiar substance. On the 16th of May the doctor took his vacation, leaving me the entire charge of the case, so that she came under my care every day. On the evening of the 16th she passed a large, flat stone an eighth of an inch thick, three quarters of an inch long, and an inch and a half in width. I was not present at the time, her father attending her, as I could not get there. She went quietly along until the 19th, when I saw her in the morning, and she informed me that a stone was starting and would not doubt be delivered that night, and she would like me to be present at the birth. She had become so acute to all the trouble, and was such an expert in it, that now she had reached the stage where she was able to describe accurately the shape, size, etc., of the stone which was coming, as soon as it entered the ureter. Upon my arrival at the house in the evening I was told she had just passed a good-sized stone, which I saw, and which was lying in the chamber along with the peculiar material mentioned, and also some gritty, fine sand. On this visit I had made up my mind that it was a case of malingering, as a day or so previous I had handed one of the latter stones to a friend of mine who was a geologist—the particular stone having been taken from the patient by the attending doctor—who upon examination of it asked me if it python pyrites, or fool's gold, abounded in renal calculi, as he had found some in it; and also that the stone was one of lime formation similar to many that could be found in that locality. Having decided to prove the case, now that I had an opportunity, I took very careful notes of all the proceedings from the time of my arrival, 7 p. m., until the following morning, and therefore will proceed from here on with reproductions from them. I should also add that the patient had obtained an insight as to the correct time the stone would pass as well as the shape, etc., before spoken of.

May 19th. 7.30 P. M.—Was shown stone No. 1, and the material alleged to have been passed, both in a perfectly dry condition, without any trace of water in the chamber. Pulse 96, although she is breathing hard and face still flushed, having just come out of a convulsion. Her father has driven to the village about a quarter of a mile away. I talked with the patient concerning the shape and size of the stone which was to be passed, but she could not describe it, as it had not yet advanced far enough. Gave an eighth of a grain of morphia hypodermically.

8.30 P. M.—Her father just returned from the village. Both of us went down to get supper. The servant, a deaf-mute, leaves us to go up stairs to the patient, returns in a few minutes to take a cup of tea up stairs, then returns again with cup empty.

9 P. M.—I went up stairs, when patient requested me to make her a lemonade, which I did, and which she drank. Only slight pain present. Some visitors called her father down stairs, and he showed them stone No. 1, as he has shown all the other stones to everybody, so that the entire village is talking about the case.

9.15 P. M.—Father returns up stairs, sits down, and lights his pipe, as smoke does not trouble her. Pulse 80; also continues to use a little chloroform, as she had been accustomed to doing while the pain lasted. The bottle held four ounces of chloroform, which I filled when I arrived at 7.30 p. m. As we sit here she is still using chloroform, and her face shows signs of extreme agony.

9.30 P. M.—Went down stairs and passed outside to get a little fresh air, as it was very close in her room. I left her resting very quietly, and apparently just about to sleep. As I walked up and down, thought I heard her voice; quietly took position in the shadow of a large tree which was about four feet from the house and in a direct line with her window, the shadow being formed by the light from her room lamp. I stood here for over half an hour and heard several sentences referring to myself. Among them: "I wish we had not let Dr. Parker take the stones"; then some more indistinct words. Imagine my surprise at being able to hear the patient talk in such a loud tone that I could hear her down there, while she had to whisper in her room. I then walked to the house of the gentleman for whom her father was the farmer, and seeing him asked him where I could find any slate like the stone I had in my possession and which had been passed in the afternoon. He told me of a place down near the well and also along the road to the village. He questioned me concerning the case, and although I told him of my suspicions he did not agree with me.

10.15 P. M.—Returned to my position near the house and heard the father and patient still conversing.

10.30 P. M.—Went up stairs; the patient was slightly uneasy, complaining of pain in the right side. The entire four ounces of chloroform had disappeared. Partially refilled the bottle. Footsteps were heard approaching the house and voices were heard outside below. The father went down to see who was there; the patient recognized the voices as those of the wife of the owner and a maiden lady who was a great gossip. They came in, and as the patient heard them she requested me to sprinkle chloroform over her so that they would smell it, and I was to hold a handkerchief over her face as if she was being anesthetized, while her part was to pretend to be asleep. The ladies came upstairs, stopped at the door of the room, and I could see them looking at the patient through the crack in the door; finally they went down stairs. Again footsteps were heard approaching, when the same little farce was enacted again. Upon their leaving, the patient began talking to me, and told me that she had been favored by another dream—namely, that two more very large stones would come away; they were to be the last, and then she would get well. The father returning, I went out again, as everything seemed quiet.

11.30 P. M.—Took the stone passed and the material (unknown) which accompanied it, as well as a stone I picked up in the garden, and returned to the proprietor's house; went in and told him and his sister my opinion of the case, showing them both the stones and also the material; still their faith in the patient was unshaken. Then I asked the sister if she had been at the house that evening, and when she acknowledged it, I asked her what had occurred, and how they supposed she was under the influence of chloroform which I was administering and the odor of which they detected. I asked if they had sent in any food to the invalid. They replied they had, consisting of asparagus, chickens, and other delicacies, which the deaf- mute had told them she had eaten with a relish, and yet all this time she had denied to as having eaten anything, taking only a little milk, while solid food was out of the question.

12.15 A. M.—Returned to the house, where everything was quiet, her father having retired. After a short time her father entered the room, and as I sat by the bedside I asked the par-
tient to give me the length, breadth, and thickness of the stone that was coming, when she drew a diagram an inch and a half in length, three fourths of an inch in its greatest breadth, and an eighth of an inch in thickness, in the presence of her father, which she gave to me. Her father retired again, while I still sat up with her.

12.35 A. M.—Several convulsions, and all through the most violent ones the pulse remains at 80. I now and then would read a little or write notes; sometimes both of us were talking, and yet the stone was making its way down the ureter. Every now and then would have a convulsive movement, during which she would take a whiff of chloroform. After a time they began to increase, and she was apparently suffering excruciating pain. I offered to give the chloroform and did, with the object of getting her unconscious, so that I might make an examination of the vagina, as she would not let me before, and find out if the stone was hidden there or anywhere else. After ten minutes' inhalation her arms dropped down from her head, where she had held them. The muscles all became apparently relaxed and she breathed heavily. Thinking she was under the influence of the anæsthetic, I pinched the flesh at the base of the finger-nail, to see if she was thoroughly under it, when she immediately jumped up in bed and refused to take any more chloroform. So I lost my chance of making the examination.

1.15 A. M.—Patient told me that the pain would return about 3 a.m. I then pretended to be very sleepy, and with my head resting on the footboard of the bed, and my eyes half closed, faked sleep. She watched me closely until from my pretended heavy breathing she presumed I was asleep. Immediately the convulsive movements ceased, she reached out for a glass of milk she had on a chair near at hand, drank it, and refilled the glass from a pitcher which was also on the chair. I then stretched myself, yawned, and awoke slowly, when she immediately went on with her convulsive movements. These continued off and on until a quarter before four. Meanwhile we had several conversations, all concerning the stone and its passage and the wonderful dreams she had had.

3.35 A. M.—Pains becoming exceedingly violent, patient desired me to call her father, which I did (an excuse to have me leave the room, as I could not call him without doing so). He came in, helped her on the chamber, which he first rimed out (to show there was nothing in it) and placed under her while she was in the bed. While she was having the severe pain caused by the passage of the stone from the bladder, into which it had fallen, as she said, while I slept, the pain was not so severe as it had been in its passage from the kidney. She sat upon the chamber with both hands under the bedclothes, her father supporting her back, and as I turned on my heel to note the time, she gave a loud scream. I heard the click of the stone as it dropped into the chamber, and she sank back upon her pillow apparently exhausted, while the stone was produced in the chamber, along with a large amount of supposed hippuric acid, all in a perfectly dry condition, together with the gritty, sandy soil. During all these fearful agonies which she suffered, also during the exhaustive period, her pulse was 80, full and strong. The exhaustive period lasted for fully half an hour, and yet the pulse showed no change.

5 A. M.—Retired to my room down stairs, where I completed the foregoing notes, leaving the patient with her father. After a short time I crept softly up stairs and, looking through the crack in the door, found the patient quietly sleeping alone, her father having left her. Quietly slipping into the room, I felt her pulse, which was still 80, good and strong. Leaving her, I found her father asleep in his room, and as it was now about daylight, I walked around by the well, and picked up stones which could be easily cut to any desired shape, and whose character was the same as many of those that had been passed by the patient. Then I turned in for a short nap.

6.45 A. M.—The father just woke me up. Went up stairs and found the patient all right, then went down to breakfast. The father, the little girl (the patient's daughter), the deaf-mute, and myself were the only ones in the house, save the patient, and we all took breakfast together, none of us leaving the room.

7.30 A. M.—Returned up stairs, found the patient's hair neatly done up, the bed nicely made, and the room straightened up in a general way, while on going down stairs we had left everything in considerable disorder.

Knowing how to use the deaf-and-dumb signs, I was able to carry on a conversation with the deaf-mute, who informed me that the patient was in the habit of having three eggs cooked daily for her, which she ate, or at least which disappeared; also that on the previous evening she had taken up three extra eggs which she had cooked for her while I was out. Upon leaving the patient at 8 a.m. in a comfortable condition, I heard her call her little daughter by name very distinctly while she was near my buggy in the road, which was pretty good for a person who could only talk in a whisper. In passing along the road to the village—a road that the father had to pass every day of his life, and which he had also passed the previous evening—I noticed the hedge of reeds I was told of, and from which I gathered many specimens identical with those which she passed, and which I now have in my possession. Upon arriving at my office tests were made with whites of hard-boiled eggs, which corresponded to the tests made for hippuric acid (supposed). I also whittled or cut a stone out of one of my specimens which I returned to the father in place of one of the original ones, of which she had made the drawing, and which he could not tell from it, meanwhile retaining the original stone. I reported the circumstances of the case to the attending physician upon his return, but he only became exceedingly provoked at both my father and myself, and refused to believe them. The father of the patient denied everything, and even went so far as to maintain that I was under the influence of liquor—peculiar delirium of mine that.

What has ever become of the case I do not know. But surely it is one of the most peculiar cases of malingering I have ever met with in my practice. All further notes or incidents of the case were lost sight of, and, although I have heard that the case passed along to recovery (without my aid), I never really knew. The father and daughter were combined together to deceive for some particular reason, I know not what—whether to become, as I first stated, a medical freak, or for some other more debased object, I can not tell.

November, 1894.

The Philadelphia Pathological Society.—At the semi-annual conversational meeting, to be held on Thursday, April 25th, at 8.15 p.m., in the hall of the College of Physicians, northeast corner of Thirteenth and Locust Streets, Dr. George Dock, of the University of Michigan, will deliver an address entitled Trichomonas as a Parasite of Man.

The Association of Alumni of St. Mary's Hospital, Brooklyn.—The third annual meeting will be held at the rooms of the Medical Society of the County of Kings, No. 356 Bridge Street, on Monday, April 22d, at 2.30 p.m. Papers are to be presented by Dr. E. G. Mason, Dr. J. Richard Kevin, and Dr. William E. Sullivan.
BLOOD EXAMINATIONS REGARDING THE MALARIAL ORIGIN OF ZOSTER.

BY JAMES M. WINFIELD, M.D., BOSTON.

The uncertainty regarding the aetiology of zoster makes it a disease of considerable interest to the neurologist as well as to the dermatologist. As each new theory is carefully investigated and found inadequate, others are advanced.

A brief résumé of the views taken by dermatological writers will serve as a suitable introduction to this paper.

In the older works, such as those of Cazenave (1), Erasmus Wilson (2), and Tillbury Fox (3), we find that zoster was considered a disease of childhood, that it sometimes appeared to be of an epidemic nature, and that outbreaks were often influenced by certain atmospheric and seasonal changes. Bazin (4) held the opinion that arthritic affections, such as rheumatism, were important aetiologic factors, particularly when it occurred in children.

The recent writers—Duhring (5), A. R. Robinson (6), Crocker (7), et al., agree in the main with the older observers. Hyde (8) puts malaria among the possible causes. Of late years there has been a growing belief that true idiopathic zoster was of infectious origin. Kapossy (9) supports this theory on the following grounds: That the disease generally occurs in small epidemics, and that it rarely attacks a person twice in a lifetime. Érb (10) says zoster is only the local manifestation of a constitutional malady, derived from some specific germ. Landouzy regards it as an acute infectious disease, and that change of weather and season is probably necessary for the development of the pathogenic germ. No specific organisms have yet been isolated; although many have been described by various observers, none have thus far responded to control tests.

Bramwell (11) has succeeded in cultivating several distinct organisms from the vesicular fluid; but, as the subject is still under investigation, he has not given his conclusions. Pfeiffer (12) and Wasielewski (13) consider these bodies from the zoster vesicle to be of the protozoan order; but Hartzell (14), of Philadelphia, has found these so-called psorosperms in traumatic herpes as well as in the idiopathic, which would go to show that these bodies were the result of inflammation, rather than the cause of the disease.

It will be seen from this short reference to authorities that the aetiology of zoster is still uncertain. While all agree that it is a neuropathic disturbance depending upon some irritation of the nerves, what this irritant is remains undetermined.

My attention was called to the possibility that zoster was of malarial origin by observing that many of the patients lived in districts noted for malarial diseases, and that quinine would often mitigate the severer symptoms. Actual examinations of the blood of zoster patients for the plasmodium were begun about a year ago, and, with the exception of cases like that reported by Henry Jackson (15), of Boston—which have an indirect bearing on the subject

* Read before the Medical Society of the State of New York at its eighty-ninth annual meeting.
were examined by different gentlemen, and it gives me great pleasure to thank Dr. A. C. Brush and Dr. E. H. Wilson for their kindness in helping to verify my observations.

To make a proper examination it is better to procure the blood at the beginning of the eruption; and, as quinine and probably coal-tar derivatives have a destructive influence on these germs, none of those drugs should be administered before the examinations are made. In recapitulation it will be seen that out of seven cases thus far, in three there were unmistakable evidences of malarial poison, as shown by the presence of the plasmodium of Laveran. One case was negative, one uncertain, another not examined on account of the breaking of the specimen, and the remaining one was probably rendered sterile by the administration of doses of quinine. It is thus demonstrated that nearly fifty per cent. of the cases showed the presence of malarial infection; and it is probable that some of those remaining would have presented the same could a proper examination have been made. Although the cases reported here are limited in number, still, with this undoubted evidence, the conclusion is warranted that malaria can and does produce herpes zoster. From our knowledge of the way malaria occurs, it is evident that if it causes herpes at all, it can explain the relative epidemics of zoster that have been described, though other causes may also be sufficient.

Those given in this paper were not of the epidemic type; they were the true idiopathic form occurring at all seasons of the year; hence it shows with certainty that this infection may also produce sporadic cases. It is further seen that the larved and chronic forms of intermittent poisoning are those that produce this skin affection; for, in all of those here reported, and many others in which no blood examinations were made, symptoms were observed suggestive of paludism, such as sleepiness, yawning, etc. Just how the parasite accomplishes its results can not be stated. It may be by clogging up the terminal arteries, or there may be some localised toxic effect on the intervertebral nerve ganglia, or it may be the result of a general toxemia. As it is not the purpose of this paper to discuss pathology, but to state an aetiological fact, we will leave this subject for further study.

Of the different theories of the cause of zoster, the infectious appears to have the greatest weight of evidence in its favor. From the earliest writers to those of the present day it has been a well-recognized fact that many cases of this disease occur at the change of seasons. The claim that this skin eruption attacks a person but once in a lifetime is probably incorrect; for in a disease which is in itself uncommon, recurrences would, in the same proportion, be exceedingly rare, and of late several exceptions to this rule have been reported.

Malaria has been recognized as an influencing agent in many diseases which have been aetologically obscure. Twenty years ago Yandell (17) maintained that it was able to cause nearly all the acute dermatoses. It matters not how correct his theories were, but if the miniscopic parasite had then been known, it is probable that his views regarding herpes would have been relegated from the field of speculation to that of assured facts.

In passing, a few moments might be given to the question of the identity or non-identity of herpes zoster and herpes febrilis. The identity of these affections was first defended by Bärensprung; since his time many observers have added their assent. Clinically, the two diseases differ somewhat; but if the germ that produces the facial herpes of intermittent fever can also cause a true idiopathic zoster, as the above cases show, it is clear that, in spite of the clinical variations, their aetiology is often identical. I do not wish to be understood as saying that malaria is the only poison that causes the herpetic eruption, but I think it should be placed in the front rank of aetiological factors, for it is confidently believed that the observations begun in Brooklyn will be verified in other parts of the world, especially in those localities where malarial diseases are more or less prevalent.

Note.—Since this paper was written the following additional case has come under observation:

II. S., aged forty-eight, a plumber's laborer, had been exposed by his occupation more or less to sewer gas. During the greater part of last winter he had been employed in a damp cellar, where there was an open, untrapped soil pipe. About six weeks previous to the zoster outbreak he began to have a variety of symptoms which his physician called malarial. He frequently had chills, fever, and sweating. According to his story, it appears that these phenomena did not occur with any regularity. Three weeks after—that is, three weeks before the zoster—he began to suffer from "facial neuralgia" (1). This continued intermittently until thirty-six hours before his visiting the skin department of the Long Island College Hospital, when a few vesicles formed on the ear and right side of the face. This herpetic process rapidly spread until the cervical, scapular, brachial, and upper thoracic portions of the right side were covered with a well-marked zoster eruption. Some of the older vesicles were becoming necrotic. The temperature at that time was 100° F. An immediate examination of a fresh specimen of blood revealed the intercellular and free pigmented forms of the plasmodia.

NAEVUS MATERNUS.*

By S. P. ALLEN, M.D.,

Wheisy's Point, N. Y.

From time immemorial it has been the popular belief that all navi were simply the result of peculiar longings of the mother during her pregnancy for various delicacies which are thought to bear some sort of resemblance to the so-called "mother's mark"; or else they were caused by a sudden fright or injury, the mark resembling the object at which the woman became frightened or being situated on that part of the child corresponding to the seat of the injury on the mother; or from anger, the mark assuming the form of the object at which she became enraged.

On this subject medical authorities are not agreed. Some, adhering to the popular belief as above stated, and others, discounting this entirely, hold to the theory that some, at least, of the malformations are owing to an arrest of development dependent upon a defective organization of the germ, and that others are probably caused by irritation of the nerve centers, or perhaps are due to faulty position of the fetus in utero, while still others are the result of violence inflicted upon the child during gestation. As for myself, I had always been one of the unbelievers in the popular theory until quite recently, when four cases came to my notice, two of which were of such a nature and so situated that treatment was not required and would have been useless. The others were treated successfully, and one of them was so plain a case and of so serious a nature that I deem it worthy of notice:

Case I.—Mrs. T., aged about thirty-five years, was, during her pregnancy, left entirely alone for a day at a farm house, and, being some distance from neighbors, had felt a little uneasy all day. A little before sunset she was obliged to go to the barn, quite a distance from the house, to do some chores, and just as she was in the act of opening the door she heard some one speak to her. She was startled, and looked around to see who the voice came from; not discovering any one, she became frightened and was about to run for the house when she again heard the voice, and, looking up, saw a balloon with basket attached, and a man in the basket who was trying to attract her attention. In turning suddenly she struck her abdomen with such force against the door as to cause considerable pain, but no serious injury. A few months later a boy was born with a perfect picture of a balloon and basket all complete on the abdomen, just at the same point where the mother was hurt by the barn door.

Case II.—This was caused by the mother longing for a Bartlett pear. So intense was her desire that it caused considerable anxiety on the part of her friends; but as it was at a season of the year when her desire could not be satisfied, she went without. I attended her during her confinement, and she remarked during labor that she expected the child would have a pear on it somewhere, and sure enough, when the child was born, a well-developed pear was attached to its little finger by a stem about an inch in length. The pear was of about the size of a filbert.

Case III.—This was caused by anger. Mrs. M., while pregnant, had been baking some pies and had set them out in a back room to cool. When she returned an old hound, against which she had a strong antipathy, was just in the act of making off with a pie in his mouth. She was very angry and attempted to strike the dog, but he dodged past her and escaped with his booty. In due time a girl was born, but very much disfigured. The left ear was of the shape of a dog's, and hung down in the same way; the left eye was also shaped like that of a dog; the left corner of the mouth extended farther back than the right, and in shape very much resembled that of a dog. She grew to be a young lady, and the eye and mouth improved considerably, but the ear continued to grow down, and was always kept covered with her hair; yet, in spite of all that could be done, she remained an object of pity.

Case IV.—This was the cause of so much suffering and anxiety on the part of the patient and family that I was called to treat it, and will in brief give its history and treatment:

Nineteen years ago Mrs. S., who lived in a farmhouse situated near a piece of woods, was one day skinning milk in the dairy, when suddenly a partridge flew in at the window and near where she was standing. She was so frightened that she jumped back to get out of the way, and in doing so struck her hip against the corner of the stairs with such force as to cause considerable discoloration and some lameness for a few days. The part injured was near the great trochanter on the left side. She continued to the end of her term and was delivered of a female child, perfect in every respect except for a mark at the same point on the left hip where the mother was injured, which resembled a partridge with wings extended, as the mother saw it. The girl, who was bright and promising, grew to the age of eighteen years without suffering any inconvenience from it. At this time she noticed that it was growing, and at times was quite painful—so much so that some time during April she called my attention to it. I found a dark purple discoloration of the skin, in size about two inches and a half by three inches, and in shape as before stated; it seemed to be composed of a mass of large veins situated just beneath the integument, and upon careful pressure a faint pulsation could be detected. At one point near the center the covering seemed to be very thin. I informed the family that there was danger of hemorrhage that might possibly be of a serious character, and advised the removal of the entire mass by excision. To this they refused to listen, being afraid of the knife, and thinking that some other plan of treatment would be better. They returned to their home in Cortlandt County, and the young woman went about for a few days as usual, except that she began to be quite lame and to suffer more pain, when all at once without any apparent cause, an alarming hemorrage came on. They succeeded in controlling it by compression until the arrival of the family physician, who dressed it, and after watching it for a few days told the family that he thought the opening could be healed, and advised them not to have it removed. He continued to treat her until the first of last September, but still the place refused to heal, and it had steadily continued to enlarge, except at one time during the summer, when for a few days it had almost entirely closed, but only to break down more than ever before, until the open sore was nearly an inch in diameter. Soon after this she was brought to my office again, and while there she had another hemorrhage which was quite troublesome to control, but by means of a firm compress and tight bandage we succeeded. They then told me that if I still thought best to remove it I could do so with their full consent. I said to them that since their physician did not think best to operate I would like counsel and assistance in the case, for the reason that, from the loss of so much blood and the constitutional disturbance caused by her suffering and anxiety during the summer, she was not in good condition for an operation.

* Read before the Medical Society of the County of Broome, N. Y., January 8, 1895.
Accordingly Dr. C. B. Richards, of this city, was called in consultation. After a careful examination it was thought best to remove the growth at once, as her life was now being endangered by longer delay.

After cleansing and thoroughly preparing the parts she was put under an anesthetic and we proceeded to remove the entire mass. We did not anticipate any serious hemorrhage, for the reason that it was thought to consist only of enlarged veins, and when they were emptied we believed we would have no more trouble, knowing that there were no arteries of any size near this region; but to our surprise the second stroke with the knife severed an artery of about the size of a goose quill. This was secured, but not without the loss of considerable blood, which our patient could ill afford to lose. We now thought our trouble over, for we considered this the feeder; but it was not so, for at almost every stroke of the knife I severed an artery of smaller size; they seemed to come from every direction like the spokes of a wheel, the hub being represented by the growth. We finally succeeded in removing the entire mass, which measured five inches in length by two inches and a half in breadth. The loss of blood was much more than we had expected, but was finally controlled, and the wound was closed by the interrupted suture, dressed antiseptically, and left for a week, with the hope that we might get union by first intention; but in this we were disappointed. Owing to the loss of so much blood and the patient's previous condition, only about a third of the wound healed without suppuration. The remainder filled in slowly by granulation, and at the end of about five weeks was entirely closed and in good condition. She has steadily gained in flesh and strength, and is now in much better health than for a long time before.

ABSENCE OF THE EPIGLOTTIS.

By THOMAS HUBBARD, M.D.,
TOLEDO, OHIO.

Mrs. A. H., German, aged thirty-five years, was first seen August 3, 1894. Her general appearance is that of one who has experienced considerable ill-health and malnutrition. The voice is low-pitched and rather coarse, and she speaks with some effort.

She is the youngest of six children, all living and healthy, and her parents, now over eighty, enjoy remarkably robust health. Her life has been spent on a farm. She was married in May, 1894. The maternal grandfather died of consumption, and her half-sister (same mother) died after a sickness of several years of the same disease about five years ago. She was very intimately associated with her during her sickness, caring for her and often kissing her, as she stated.

Until she was nine she was a very strong child, but was injured by overwork and exposure, and during the rest of her developmental period she was in very poor health. These facts are mentioned to call attention to the inherited vitality and the remote and also the probable determining factors in the disease which followed. About a year after the death of the sister she again declined in health, more or less severe pulmonary symptoms predominating. She coughed badly for two years, and then had an attack of la grippe. Her scarred chest bears witness to the heroic treatment received at this period and tends to confirm her statement as to the diagnosis. She states clearly that all expected her to die of consumption. Soon after the la grippe her throat began to trouble her, described in her own language as "a burning raw place low down in her throat, like a spot with no skin on it." Gradually the pulmonary symptoms subsided as the throat became worse. For a time she was quite house, and then the distressing symptoms abated and left her with a sensation of lateral tension or slight constriction in her throat. For two years she has been quite free from cough, but has not been able to eat salty or highly spiced foods or pickles, or take cold drinks, without experiencing a burning sensation for several hours. There has been no trouble with deglutition whatever, except as above mentioned.

Examination of the thorax reveals dullness over the right apex, with tubular respiration over a limited area, and tenderness on percussion over both apices. At present she considers herself in very fair health, but she is extremely cautious, especially in the matter of diet, since slight indigestion causes aggravation of the throat irritation.

Laryngoscopic examination shows that the epiglottis is almost entirely gone. A small stamp remains about a centimetre in breadth and about half a centimetre in length. The upper margin is somewhat granular, and all of the edges are angular. There is some tension of the lateral epiglottidean folds, but the intralaryngeal structures seem normal in their relations. The mucous membrane over the arytenoids is somewhat thickened and hyperemic.

The history would indicate that the loss of the epiglottis was recent. Its appearance is rather opposed to the idea that it may have been a congenital defect, since in that case it would have been round and smooth at the edges. Six months' observation shows no material change in her condition. There are at present no signs of active tubercular disease whatever.

Syphilis, congenital or acquired, is excluded in so far as it is possible. It is difficult to decide positively as to the cause of the condition of the epiglottis, but the study of the case inclines me to ascribe it to tuberculosis or possibly lupus. Further observation may clear up this matter.

SNELENN'S TEST TYPES.

By G. W. GROVE, M.D.,
KANSAS CITY, MO.

I should like to call attention to certain errors in the size of the test type commonly used by oculists in ascertaining visual acuity. If any one will observe by actual measurement the size of the type on the cards put out by different firms, he will find that there are variations in the size of the test letters which will produce errors too great to be ignored in practice. I have frequently measured these types in private offices and in New York hospitals, and found them usually wrong.

These types are generally arranged for a distance of twenty feet in testing an eye; the angle each letter subtends is five minutes, as indicated by the number on the card. Thus No. 200 at two hundred feet subtends an angle of five minutes, and \( \frac{200}{200} \) or \( \frac{1}{200} \) is the visual acuity (V.). No. 20 at twenty feet subtends an angle of five minutes, and \( \frac{20}{20} \) or 1 is V. Now, it is important that these letters be of correct size; if they be too large, V. is less than he have calculated; if too small, then V. is greater than we have reckoned. My observation is that Snellen's types are too large—a fault of the printer.

In the following table, column A shows the distance in feet, as indicated on the card, at which the letter subtends an angle of five minutes of arc; B shows the false size of these letters in millimetres; C shows the distance at which
this false size of type must be placed to maintain correct
test of V ; and D shows the size in millimetres the type
must be in order to be correct:

<td>9</td>
<td>2</td>
<td>0.8</td>
</tr>
</tbody>
</table>

If No. 50 is taken at twenty-four millimetres instead of
21.8 millimetres, as shown in column A, then V., instead of
being or 0.4, is or 0.36; and if No. 50 is taken at ten
instead of 8.75, then V. is or 1 instead of or 0.8,
which are errors too great to be passed over.

By reference to column D any one can take a tape line
or ruler, graduated in millimetres, to measure his own type
to ascertain whether it be of correct size. By columns G,
E, and F, whose numbers I have carefully calculated, any
one may measure or select type for visual acuity from to 1.
Thus it is seen from column E that and and so on. If the type as indicated in column F is
greater or less than there given, then the visual acuity
would be wrong.

This question of the false size of test letters so com-
monly used I have deemed of sufficient importance to call
to the attention of oculists both in their private and hos-
pital practice.

An American Milk Yarn.—E. Marsh, of Mineral Town-
ship, in America, comes to the front with a story that is both
wonderful and unique, but true in every detail. About five
weeks ago a Durham-Albemarle cow, aged two years, gave
birth to a calf, and they began to milk the cow, but were thun-
derstruck when they discovered that its milk was black. The
calf, however, was given upon the milk, and last week Mrs.
Marsh, having overcome her prejudices, decided to try some of
the milk. It tasted the same as other milk, only it was much
richer, and by leaving a crock of it to set four hours nearly
two inches of cream, a little lighter in color than the milk,
would rise to the top. Two gallons of the cream were churned
and four pounds of butter were secured. The butter was ex-
amined by a chemist, who pronounced it perfect butter only in
color, and gave the reason for the color something yet unknown
to science in the blood of the animal. The butter much re-
sembles coal tar and has a delicious taste. People are coming
from far and near to see the freak, and Mr. Marsh has been offered
big sums for the cow. He has decided not to sell her, how-
ever, in the hope that he can raise some more stock of the same
kind. A roll of butter will shortly be sent to Franklin and
placed on exhibition. The milk makes fairly good ink and the
cream might be used for printers' ink.—Food and Sanitation.

Change of Address.—Dr. Cornelius M. O'Leary, to No. 8
Convent Avenue, New York.
MINOR PARAGRAPHS.—ITEMS.

A REMARKABLE INSTANCE OF RECKLESS ASPERSION.

The Lancet's Berlin correspondent tells of the prosecution of a quack who had undertaken that within three months he would cure a woman far gone with tubercular consumption. The woman died in a fortnight. At the quack's trial for fraud one Dr. Long, described as "medical officer at the Berlin law courts," was asked by the defendant's counsel if it was not possible to cure consumption. Not content with having answered that it would be "as easy to fetch a star from the sky as to find a universal remedy for this illness," he is reported to have remarked, in reply to the counsel's allegation that his client was "as persauded of the curative effect of his remedy as Professor Koch was of tuberculosis," that in his opinion they were both, Dr. Koch and the defendant, "guilty of the same crime," and that he did not understand the public attorney's "prosecuting the little and not also the great thieves."

THE BUFFALO MEDICAL AND SURGICAL JOURNAL.

The accomplished and genial editor of this well-known and highly esteemed journal, Dr. William Warren Potter, informs us that it will have completed in the course of a few weeks the term of fifty years of publication, and that he intends to mark its semi-centennial anniversary by increasing the number of pages of reading matter in each issue from sixty-four to eighty and by making "other improvements that will contribute to its efficiency and keep it abreast of the professional progress of the period." Medical journals, like wine and violins, are prone to grow better as they grow older, and the Buffalo Medical and Surgical Journal shows manifest evidence that it conforms to the rule in this respect. We wish it centuries of ample prosperity.

THE DISCHARGE OF PATIENTS FROM LUNATIC ASYLUMS.

A new statute has been enacted in the State of New York governing the discharge of inmates of the State hospitals. It provides that the managers may discharge a patient whenever, in their opinion, the public interest will not be affected injuriously by his liberation, and that, on their declining to do so, a judge of a court of records may order the discharge, but, however, until the superintendent has been heard and the patient's history read.

"INDUCED" MALPRACTICE.

A recent example of newspaper medicine is the outcome of a coroner's inquest in a case of alleged criminal abortion. The deputy coroner is made to testify as follows: "The girl, he found, had died of endometritis, peritonitis, and double pleurisy, caused by malpractice, but whether it was induced or not he was unable to say. In his examination he said that the autopsy revealed that medicines had not been used."

ITEMS, ETC.

The Brooklyn Case of Death after the Use of Diphtheria Antitoxine.—We have been asked to publish the following documents:

"Brooklyn Health Department.

Hon. Z. T. Emery, M. D., Commissioner of Health.

Sir: I have the honor to report that yesterday, April 1st, I procured from Schulze-Berge & Koechli two bottles of Behring's antitoxine No. 2, containing a thousand immunity units, sealed under the date of January 30th, operation No. 159, being a portion of the same lot as used in the case of Bertha Valentine. Of this serum one cubic centimetre was injected beneath the skin of a guinea-pig weighing four hundred and twenty grammes at 4.30 p.m. The animal suffered no inconvenience from this injection. At the time two and one half cubic centimetres of the same serum were injected directly into the ear vein of a large rabbit. This animal suffered no inconvenience. I also obtained from Dr. Clayland, the coroner's physician, about one ounce of fluid blood received in a sterilized bottle from the right auricle of the heart. One half of this blood was given to the chemist of the department for the chemical analysis. Direct microscopic examination and cultures from this blood showed it to be free from micro-organisms. Speculative theories may be advanced as to the cause of death in this case, the true cause not having yet been determined, but the above experiment, conforming as nearly as possible to the actual condition, demonstrates that the cause was not inherent in the antitoxine.

Sincerely yours,

[Signature] "E. H. Wilson, M. D., "Chief Bacteriologist."

Bacteriological Laboratory,
"New York City Board of Health, April 2, 1895."

"This is to certify that, in view of the sudden death which recently occurred in Brooklyn after the administration of Behring's diphtheria antitoxine, and at the request of President Wilson of the New York City Board of Health, in the absence of Dr. Biggs, I obtained from Messrs. Schulze-Berge & Koechli, the American agents for the remedy, two vials of the antitoxine from the same lot, operation 159, as that which was employed by Dr. Kortright in the case alluded to. I have submitted both vials to thorough tests at the bacteriological laboratory of the board of health by injecting excessive doses into guinea-pigs and rabbits without producing in the animals any deleterious effects whatever. Specimens from both vials were also submitted to bacteriological tests, and were found to be absolutely free from living germs of any kind. These results, taken together with the fact that the New York City Board of Health has employed this same make of antitoxine in a considerable number of cases with only the best of results, lead me to express the opinion that the unfortunate results which followed its administration in the case referred to can not be attributed in any way to the antitoxine which was employed."

W. H. Park, M. D.,
"Assistant Director of Hospital Bacteriological Laboratory, N. Y. C. B. of II."

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending April 2, 1895:

The Cleveland Medical Society.—At the meeting of March 22d the special order was a lecture by Dr. M. Allen Starr, of New York, on The Mechanism and Causation of Nervous Diseases.
Cold in the Treatment of Pneumonia.—Dr. Thomas J. Mazey, of No. 1829 Spruce Street, Philadelphia, asks us to publish the following:

"To the Members of the Medical Profession: My last paper, on ice-cold Applications in Acute Pneumonia gives a record of seventy-four cases so treated, and only two deaths. Being desirous of making a full collective report on this subject, I take the liberty of asking those who have tested this measure to kindly give me the result of their experience with it. Full credit will be given to each correspondent in the report which I hope to publish."

The Late Dr. Thomas F. Parkes, of Brooklyn.—By order of the Kings County Medical Association, a committee of that body has prepared the following:

"Thomas F. Parkes was born in Brooklyn, N. Y., July 30, 1833. He received his education in the public schools of this city and in Wright's business college.

"He attended one course of lectures in Bellevue Hospital Medical College and two in the Long Island College Hospital, where he made abiding friends, including among them his professional associates, and where he acquired proficiency in the practice of his profession, being mindful of his patients and faithful to himself in the improvement of his opportunities.

"He was fortunate in the choice of his field for private practice and unusually successful in acquiring a paying business.

"He was single, and had his office and home with his parents at 603a Halsey Street, where he died.

"The cause of his death was somewhat obscure. It was reported to be 'oedema of the glottis.' Dr. Maine, of this association, was with him in consultation the night before his death, when he appeared to be in his usual health. His bereaved mother said that he came home from a patient about one o'clock in the night, and that she heard him pass the door of her room to retire about two o'clock, without a sound to indicate sickness. He called to her about an hour later and when she entered his room he was struggling for breath. Dr. Madison and Dr. Clowmizer were summoned, but all efforts failed to give relief, and he died about two hours later, at 5 A.M., December 21, 1894.

"In his death this association has lost a member of promising usefulness and is reminded of the dangers and uncertainties which environ all physicians."

[signed.]

"W. N. Leighton, Committee."

"F. C. Raynor, Committee."

"H. C. Riggs."

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 24 to March 30, 1895:

GIBSON, Joseph R., Lieutenant Colonel and Deputy Surgeon General. The leave of absence granted him on account of sickness is still further extended six months on surgeon's certificate of disability.

PONDERSTON, Jefferson D., Captain and Assistant Surgeon, is granted leave of absence for one month.

SHANNON, William C., Captain and Assistant Surgeon, is granted leave of absence for three months, to take effect on the expiration of his present sick leave, with permission to leave the United States during May and June, 1895.

STILES, Henry R., First Lieutenant and Assistant Surgeon. The extension of leave of absence granted him on surgeon's certificate of disability is still further extended two months on surgeon's certificate of disability.

Society Meetings for the Coming Week:

MONDAY, April 8th: New York Academy of Medicine (Section in Ophthalmology); New York Academy of Sciences (Section in Chemistry and Technology); New York Medical Historical Society (private); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Maine Academy of Medicine (Portland); Burlington, Vt., Medical and Surgical Club; Norwich, Conn., Medical Society (private); Shelby County, Indiana, Medical Society.

TUESDAY, April 9th: Medical Society of the State of Tennessee (first day—Nashville); New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Jefferson (quarterly—Watertown), Oneida (annual—Utica), Ontario (quarterly), Rensselaer, and Tioga (Owego), N. Y.; Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Bergen (annual—Hackensack) and Cumberland (annual), N. J., County Medical Societies; Fairfield, Conn., Medical Association (annual); Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Ky.

WEDNESDAY, April 10th: Mississippi State Medical Association (first day—Jackson); Medical Society of the State of Tennessee (second day); New York Pathological Society of the State of Tennessee; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Society of the County of Albany, N. Y.; Tri-States Medical Association (Port Jervis), N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society; Kansas City, Mo., Ophthalmological and Otological Society.

THURSDAY, April 11th: Mississippi State Medical Association (second day); Medical Society of the State of Tennessee (third day); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; New York Laryngological Society; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia; New London, Conn., County Medical Society (annual).

FRIDAY, April 12th: Mississippi State Medical Association (third day); New York Academy of Medicine (Section in Neurology); Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, April 13th: Obstetrical Society of Boston (private).

Births, Marriages, and Deaths.

Died.

CLETTERBURG.—In Morristown, N. J., on Thursday, March 28th, Dr. Austin S. Clutterbuck, aged thirty years.

FISHER.—In New Orleans, on Tuesday, March 26th, Blanchie Eliza, daughter of Dr. and Mrs. Milton Randolphi Fisher, aged three years and four months.

GROOMS.—In Wilmore, Kentucky, on Wednesday, March 27th, Dr. S. H. Grooms.

JOYCE.—In New Orleans, on Monday, March 25th, John Power, son of Dr. and Mrs. P. A. Joyce, aged seven months.
Letters to the Editor.

THE ANTITOXINE TREATMENT OF DIPHTHERIA.

Cleveland, Ohio, April 1, 1895.

To the Editor of the New York Medical Journal:

Sir: Permit me to submit a brief note of an outbreak of diphtheria in the Summit County Children’s Home at Akron, Ohio.

The home contains sixty children, varying in age from two to fifteen years, and fifteen attendants, and Dr. L. S. Elbright, health officer of Akron, is the physician in charge.

After making a preliminary bacteriological examination of one of the cases I went to the home on Dr. Elbright’s summons on March 30th and found one boy convalescent after a week’s severe illness; another boy, sick three days, dying of profound toxemia; and three girls, ill ten days, with pronounced symptoms of a severe diphtheria. The boy lived but six hours after my visit.

Therapeutic injections of the diphtheria antitoxine obtained from our (Wooster Medical College) horse were given to the sick children, and immunizing injections were administered to all the children and attendants in the home (seventy in number).

One new case developed on March 31st, and was treated with antitoxine. In forty-eight hours a remarkable improvement was observed in the patients receiving the therapeutic injections—marked diminution of fever and pulse and complete disappearance of membrane from the throat. To-day (April 1st) the sick children are wonderfully improved.

Bacteriological examinations were made in all these cases, and diphtheria bacilli identified. No new cases have developed among the immunized individuals, though there were several suspicious cases at the time the injections were made.

Thus far we have been unable to trace the source of the disease, which is entirely confined to the children in this institution.

There is little reason to doubt that the prompt and liberal use of antitoxine will save this home from a devastating epidemic of a severe type of diphtheria.

A. P. Oelmacher, M. D.

DAMAGED DIPHTHERIA ANTITOXINE.

Nursery and Child’s Hospital, New York, March 21, 1895.

To the Editor of the New York Medical Journal:

Sir: Physicians should be warned against a large quantity of Behring’s antitoxine serum at present on the market in New York that is unfit for use. Instead of being clear, transparent, and of a pure amber color, as it should be, many bottles are sold containing a cloudy opaque serum that is slightly more milky-looking than mucilage, but still resembles it. Undoubtedly some chemical or physical change has taken place, due, perhaps, as some of the dealers suggest, to prolonged freezing during transportation from Germany. Examination shows no bacterial or fungous growth to be present. Its antitoxic properties, however, must be to a great extent or entirely destroyed; and it should under no circumstances be used, as otherwise unwarranted disrepute might be brought upon this new method of treatment.

Each bottle must be examined carefully before using. Antitoxine serum, when kept cool and in a dark place, can, as a rule, be preserved in good condition for a number of months; if, however, it spoils, a cloudiness will immediately appear and make this change easily recognizable.

James Jay Mapes, M. D.

MEDICAL ADVERTISING AND THE MAIL.

New York, March 28, 1895.

To the Editor of the New York Medical Journal:

Sir: I received to-day (in common with many other victims, I suppose) a pamphlet containing some twenty reproductions of photographs of syphilitic skin lesions. Many of the pictures were of men stark naked, and showing uncommonly well-developed genitalia. One picture showed the genitalia, but little of the man.

This pamphlet, issued to advertise some proprietary nostrum, was sent by mail to my house, and lay for a while on the table of my waiting room in an unsealed envelope, so that any woman or child prompted by curiosity might easily have inspected it, which they would have been all the more prone to do since the wrapper was marked in large letters “for medical men only.”

While photographs of this kind have a legitimate place in systematic works on syphilis, to use them for purposes of commercial exploitation is disgusting, and to thrust them into a man’s house in such a way that any member of his family—the women, the children, and the female servants—may easily get hold of them, is a signal invasion of his rights.

I have sent the pamphlet, with the wrapper as I received it, to the Postmaster-General at Washington, with the request that the Post Office take means for the abatement of this nuisance. For scarcely a week goes by without there arriving by mail, in open envelopes, pamphlets marked in large letters on the covers, “ Painful Menstruation,” “Sterility,” “ Impotence,” or some such title calculated to arouse curiosity, and it is some trouble to be obliged to tear these into pieces small enough to be useles before throwing them into the waste basket. But pamphlets of this sort are petty annoyances compared with the ostentations indecency of the publication received to-day.

While we may call on the postal authorities to protect us from having these things thrust into our houses in unsealed envelopes, yet the ultimate cure for this evil (steadily on the increase) must be sought in the attitude of the medical profession itself, which should nute out a stern disapproval to all who, for the sake of selling their wares, offend against decency and good sense.

Walter Mendelson, M. D.

New York, March 29, 1895.

To the Editor of the New York Medical Journal:

Sir: A letter has reached me from a medical practitioner of this city in which he complains regarding a pamphlet recently sent out by our company. This pamphlet is intended to show the therapeutic value of arsennico and mercurico. It is entitled “Twenty Photographs for the Medical Profession Only,” and it means exactly what it says. My response to the complainant will be found hereina. May I ask that you publish it?

Charles Rogen Parmelee.

[Mr. Parmele’s inclosure.]

— , M. D.

“Dear Sir: Your favor of even date just received. If our pamphlet has reached other eyes than your own in your house, the writer exceedingly regrets the fact. Upon both the envelope and the pamphlet are the plain Anglo-Saxon words, ‘For the Medical Profession Only.’ Far worse illustrations appear in the medical journals and in medical text-books, and if you subscribe for any you must know that neither reach you in sealed envelopes. It occurs to us that every physician who keeps pace with medical progress must constantly receive in his office many things which are profitable to him, yet not intended
as an amusement to the household. The writer claims to possess proper instincts as to morality, propriety, and refinement; hence the wording on the envelope and on the pamphlet.

"You speak of our goods as nostrums. Permit us to say that they are not such; they are very remarkable chemical products and indorsed by professional colleagues of yours whose utterances we do not believe you will have the tenacity to question." We do not permit the laity to have any of our literature, our work being done in strictly ethical channels.

"Pardon us if we offer the suggestion that, inasmuch as your office and residence are in the same building, you do as other medical practitioners do—namely, insist that communications addressed to you be opened by you and not inspected by those to whom the communications are not addressed. If the members of a household should inspect every medical journal which comes to a physician, your line of argument would exclude the very data which make medical journals of value. How about the New York Medical Journal, the New York Journal of Gynecology and Obstetrics, the American Journal of Obstetrics, the Journal of Otaneous and Genito-urinary Diseases? All of them contain illustrations of interest to a physician, but not of profit to his family.

"Very truly yours,

"Charles Roome Parmelee."

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF CHARITY HOSPITAL,

Meeting of March 6, 1895.

The President, Dr. Adolph Riff, in the Chair.

Dr. E. Pierre Mallett, Secretary.

Gallstone.—Dr. D. E. Walker reported the case of a large gallstone causing facial obstruction at the ilio-caval valve. The patient gave a history of having had an attack of what she called congestion of the liver some two years before. She had been comparatively well until a few days before the examination, when she had been taken with an attack of gallstone colic, and in about two days had begun to have febrile vomiting, without much change in the pulse or general condition. The speaker had concluded there was facial obstruction, probably from adhesions about the gall bladder and stomach, as she complained constantly of pain in that region. An incision was made at the right of the median line in the region of the gall bladder, and a number of adhesions were found connecting the gall bladder, stomach, and intestine. A gallstone two inches long and an inch and a quarter broad was found at the ilio-caval valve, completely closing the intestine. The small end was directed downward and the stone had acted like a ball valve. It was slipped upward and removed through an incision in the intestine. It showed some blood clots on its large end, which presented a rough surface. This led him to suppose that it had probably been attached to some place in the intestine and had broken loose. The patient had recovered without any special difficulty.

The President stated that the case seemed particularly interesting from the fact that it illustrated that simple irritation did not give rise to inflammation of the verumiform appendix, for the production of which a specific poison seemed essential. In this case the gallstone did not seem to have given rise to any particular trouble, except that of simple local impaction discovered by the operator.

Dr. Brooks H. Wells asked us to the composition of the stone.

Dr. Walker stated that it was almost pure cholesterin. The history indicated that there had been an ulceration through the gall bladder into the intestine, and the condition found about the gall bladder would indicate that such was what the patient had gone through with, and that during that ulceration the large mass of adhesions around the gall bladder and stomach was formed.

Carcinoma Mammae.—Dr. Wells presented the history of a thin, anemic woman, fifty-seven years old, who had first noticed a small lump in her right breast eight years before. This lump had remained almost stationary, caused her no pain, and did not seem to interfere with her general condition. When the speaker saw her she presented a freely movable, stony, hard nodule, of the size of a hickory nut, just beneath the slightly retracted nipple of the right side. There was no appreciable thickening or enlargement of the lymphatics in the axilla or beneath the edge of the pectoralis major. The breast was removed, together with the overlying skin, the pectoral fascia, part of the pectoral muscle, and the axillary contents en masse. These included the contents of the space between the clavicle and the upper border of the pectoralis minor muscle and of that between the pectoralis major and the deltoid just below the clavicle. Convalescence was rapid and uneventful. A microscopic examination of the shot-like glands removed showed carcinomatous infiltration everywhere. This proved very certainly that the disease had extended beyond the reach of any justifiable surgical measure and that recurrence was inevitable. A condition like the one reported was to be expected in any case where the primary cancerous nodule had existed for any considerable time, and the case strongly exemplified the fact that surgical interference to be successful must be early.

Ovarian Cyst with Twisted Pedicle.—Dr. Wells had first seen this case in consultation with Dr. Mallison and Dr. Westerfield. The patient had had a tumor recognized as cystic for some months. Three days before, she had suddenly been taken with very severe pain in the abdomen, the tumor had rapidly increased in size, and she had had signs of peritonitis. When she was seen the pulse was rapid and wiry, the temperature 102° F., the abdomen above the umbilicus tympanitic and everywhere excessively tender. She had had large doses of morphia to quiet pain. The diagnosis was made of death of the cyst from twisted pedicle and beginning peritonitis, and an immediate operation was advised. On opening the abdomen, the cyst was found black and with a peculiar sti'f feeling to its walls, which were filled with coagulated blood. There were universal recent adhesions, not only to the cyst wall, but over the entire contents of the abdominal cavity, which also contained a considerable amount of pink, fleshy serum. The cyst was removed and the visceral adhesions were broken up by the hand passed into the abdominal cavity. The peritoneal cavity was washed out, a gauze drain inserted, and the wound closed. There was little shock. No opiate was allowed, and the bowels were moved by fractional doses of calomel after twenty-four hours. The temperature and pulse became normal after forty-eight hours; the gauze drained profusely for four days, and was removed on the sixth. The wound healed throughout sceptically, and the patient was allowed to get out of bed on the sixteenth day. She was now apparently perfectly well.

The President asked the speaker if he had meant to say that in such cases as the one he had reported, the operation was not worth doing.

Dr. Wells said the point he had wished to make prominent was that in cases of carcinoma of the breast the only safe operation was an exteensive and early one.
The President spoke of having been advised, when at Charity Hospital, not to cut away too much skin in operating for malignant tumors of the breast, advice opposed to that advocated by Ferguson long ago, and also opposed to the general custom of the present time. A case of his in which Dr. Frederick Lange had recently operated all the suspected tissues had been thoroughly removed, and the skin cut away quite extensively, but in spite of all this cancer had developed in the cicatrix soon after. As to a point in diagnosis and prognosis, he cited a point made by Billroth, who had found benign tumors in a certain class of large-breasted, stout, hysterical women; such tumors did not need to be removed, and the women might be spared the mortification of mutilation. One should be careful not to delay necessary operations, but one ought to be sure of the diagnosis before operating.

Dr. R. C. Newton spoke of a tumor that had been removed from a young woman. She had been married and had a child, and the tumor had proved to be quite harmless, but from anything the speaker could tell it might have been carcinomata.

Dr. J. Blake White spoke of medical treatment for tumors of the breast, and cited a case of his where the tumor when first seen had been of the size of a hen’s egg and very indurated. The patient was thin, anemic, and nervous. The speaker gave her chloride of gold, and at the end of six months the tumor was of less than half its former size, had lost its indurated character, and had softened materially, and the speaker felt assured that within sixty or ninety days more it would entirely disappear. He spoke of the chloride-of-gold treatment having been used in another case where the growth had entirely disappeared. He thought the great point was accuracy of diagnosis, for if the growth was undoubtedly malignant, internal treatment would not avail. Nevertheless, he had seen cases, presumably malignant, which had been benefited. But in such growths as he had described, that appeared to be malignant but were not, an operation would not be required. He thought a conservative course to follow would be to place the patient upon such internal treatment as had been described, and if in a reasonable time the growth was not affected thereby, recourse to the knife would be the proper procedure.

Dr. Wells said that in the case reported by the president the recurrence of the disease (in the cicatrix might have been caused by infection from the fascia or part of the pectoralis muscle or some portion of fat that had not been removed. There were often tiny cell nests scattered through the fatty tissue underneath the skin and in the fascia or between the fibers of the pectoralis muscle. As to Dr. White’s remarks, of course one would not advocate an operation unless he was reasonably sure of his diagnosis. The age of the patient was an important factor; in a woman over thirty-five one looked with suspicion on a new growth of any kind.

**MOBILE SPLEEN IN AN INFANT, CAUSED BY MALARIAL ENLARGEMENT.**—Dr. Charles J. Proben had presented the case at a recent meeting of the society. An infant, aged thirteen months, a foundling, on admission to the hospital, had been vigorous, well developed, and without any apparent blemish. After some time the baby lost flesh and became anemic, cross, and irritable. Its miserable condition was attributed to defective nursing, and it was given to another nurse, with the same result. Aside from the extreme irritability and frequent rises of temperature, nothing was noticed until the nurse discovered a swelling on one side of the abdomen. This unilateral swelling, after a careful examination, was pronounced to be a large hypertrophied spleen, occupying one half of the abdominal cavity. The osseous system of the infant revealed certain changes caused by rickets. The author thought very large spleens in infants, after excluding neoplasms, especially carcinoma, sarcoma, also cysts and abscesses, were due to three causes: leukocytoma, malarial poisoning, and syphilis. He thought enlargement of the spleen in children could only be positively diagnosed by palpation; perspiration was too uncertain and dubious. In the case reported leukocytoma had been excluded by the absence of large glands, either apparent or hidden, also by a microscopic test of the blood. Syphilis had been excluded by the absence of any lesions of the skin, mucous membrane, teeth, nose, etc. The general adenopathy was attributed to the Ricky condition of the infant. Malarial fever seemed the only feasible conclusion, judging partly from the symptoms and partly by exclusion. A microscopic examination of the blood showed pigmented bodies, transalveolar bodies, and rosette-shaped bodies in the red blood cells, also on one occasion a crescent-shaped body. The presence of the plasmodium and the large hypertrophic condition of the spleen made the case very interesting; considering that such cases were rare in New York. A proper course of quinine administration was instituted, the patient receiving two grains of the sulphate three times a day, alternating it at times with the liquor potassium arsenith. After two months the symptoms, with the fever, began to disappear, the patient improved in health, the spleen diminished until the abdominal swelling disappeared, and the spleen, about four inches long by two inches and a half wide, could be felt freely movable in the abdominal cavity, freely disposable up and down, the contour suggesting a splenic tumor loosened from its attachments. The author thought this a mobile hypertrophied spleen, and had arrived at the following conclusions: 1. That this displacement could alone be attributed to the immense size, due to malarial poisoning. 2. That the cause of the malarial infection could not be ascertained, whether fatal or later acquired from the nurse. 3. That a microscopic blood examination in cases of a doubtful character was requisite, and that even in it was negative or dubious one must resort to the therapeutic test, large doses of cinchona alkaloids, preferably quinine. 4. That intermittent fever in infants in New York city was rare; where the microscope could not decide, therapeutics must. 5. That enlarged spleen in infants was not alone due to malaria, but more frequently to rickets and other conditions. 6. That palpation of the spleen was the only feasible and certain method of diagnosis. 7. Symptoms of paludal poisoning were frequently referable to the gastro-intestinal canal, and less often to the lungs, which responded to quinine. 8. The stages of chills and sweating were absent in infants. 9. A fever of peridicial character, with enlarged spleen, other causes than malaria being excluded, demanded quinine.

Dr. White spoke of a case of enlarged spleen that he had seen in a child seven years old. The enlargement had rapidly disappeared under the use of arsenic, quinine, and iron. He believed such cases were rare.

Dr. Newton said cases had been reported that were congenital, due to malarial disease in the parents, and he thought it extremely likely that the case reported by Dr. Proben was of such a nature. The child was not in malarial surroundings when the temperature rose. He spoke of a case of splenic enlargement under his observation. In the blood there was a large preponderance of the white corpuscles. It was a case of splenomediastinal leucocytosis and offered many interesting phases for study.

Dr. Proben stated that in looking over the literature on the subject he remembered seeing three cases of fctal malarial disease. One was that of a woman suffering from malarial poisoning, who noticed in the last month of pregnancy a floating of the abdomen every night. When the child was born it had an enlarged spleen. It had seven paroxysms, and was put on the use of quinine and improved. Two other similar cases were
reported. Some observers, when they got a case of enlarged spleen, thought it was due to syphilis, but these cases had been cured with quinine.

Dr. Carr, who had examined the case, mentioned in a letter that the case was of interest from the fact that very large spleens were rare in New York, and that the plasmodium had been found to corroborate the diagnosis.

**Ringed Eruptions; a Study in Differential Diagnosis.**—

Dr. George Thomas Jackson, in a paper with this title, stated that the eruptions that appeared, either habitually or occasionally, in a ring shape, were trichophytosis corporis, syphilis, psoriasis, erythema multiforme, seborrhoea sica, pityriasis maculata et circinata, and rarely favor of the body in its so-called herpetic stage. These eruptions bore so strong a resemblance to one another at times that it was hard for even experts to make a positive diagnosis. He stated that an annular eruption was one having a well-defined raised border surrounding a patch of skin, normal or nearly so, or in which active disease had ceased. In all eruptions of the ringed variety, if two or more rings appeared near each other, they were apt to run together and form figure-of-eight or gyrate lesions, from the disappearance of the borders at the part where contact took place. Trichophytosis was characterized by a well-defined, slightly raised border composed either of vesicles, rarely seen, or pustules or papules, slightly scaly, or of small crusts, the remnants of the vesicles or pustules. Within this ring the skin might show no change or be slightly scaly, the scaling diminishing toward the center. The eruption usually lasted slightly. By examining the scales under the microscope, the fungus would be found. The disease differed from syphilis in being accompanied with itching, in having a narrow border made up of scales, vesicles, pustules, or crusts, in its scaly center, in being superficial, and in its microscopic character. Syphilis at times showed itself in rings. These did not cause the part to itch or burn. It had a well-marked, rather broad, slightly elevated border, which was infiltrated, raw, haem-colored, and composed of scaling papules or nodules. The center of the ring might be normal, scaly, crusted, superficially or deeply cicatrizal, reddened, or pigmented. Sometimes the nodules of the border would break down and ulcerate. Erythema multiforme was so unlike syphilis that it could hardly be mistaken for it. Seborrhoea corporis was situated on the chest and between the shoulder-blades, and there would also be found seborrhoea of the scalp. It had a greasy feel, and the raw-ham color of syphilis was absent. Pityriasis rosea was distinguished from syphilis by the occurrence at the same time of both macules and rings, by its lighter color, and by the chamois-leather look of the rings. Psoriasis formed rings by clearing up of the centers of old patches. The border of the ring was usually quite broad, slightly if at all thickened, its color was pinkish red, and the scales that covered it were large and silvery. The center of the ring was composed of normal skin, perhaps a little red. The scaling would be commensurate with the redness. It was commonly itchy. Erythema multiforme or erythema exudativum formed rings by the absorption of the centers of the large tubercular lesions or patches. The border of the ring was raised and its color red, the redness capable of being made to disappear on pressure and of returning promptly when the pressure was removed. The center of the ring was red or discolored on account of the partially absorbed exudate. Another form was known as erythema or herpes iris, in which there was either a purplish spot surrounded by a raised whitish ring containing fluid and outside of this a red areola, or a vesicle in the center with a purplish zone about it, a raised whitish ring containing fluid, and a red areola outside of all, or a central bulla with one or two rings of vesicles about it. Seborrhoea sica, or seborrhoea eczema, was the lichen annulatus of Wilson and the seborrhoea corporis of Dubring. It formed ring-shaped lesions on the scalp and trunk. Their favorite sites were the chest and back between the shoulder-blades. The rings were of large and small size, and there were fatty plates with more or less redness; the border of the ring might be broad or narrow. If it was broad, it would be formed of greasy crusts upon a reddened base; if it was narrow, it would be made up of a number of red points, the open mouths of the follicles of the skin; or the border might be narrow and made up of fatty crusts. The skin in the neighborhood was commonly greasy, and the inclosed area of skin looked as if varnished, being glazed and yellow. The ring shape of favor was not commonly seen. It bore a close resemblance to ringworm, but after a short time a well-marked favic cup developed. Lichen-planus papules, when they had crowded together into a patch, formed into rings by the absorption of their central papules. The ring was never of large size; its color was the peculiar violaceous color of lichen planus; the center was depressed, and the whole was scaly.

Dr. E. B. Bronson said that the most interesting thing in connection with the ringed eruptions related to their determining factors. Why should some eruptions be ring-formed and others not? The annular form was always due, probably, either to a parasitic or to a neuropathic factor. Perhaps the simplest type of this form was ringworm. In this case the disease began as a minute spot or papule, and as it gradually advanced at all points of the periphery alike while healing in the center, by the law of chances there would result sooner or later a ring. The parasitic winged eruptions always developed in this way. When the eruption began as a ring it was doubtless the result of a neuropathic cause, as, for example, in annular erythema. But in some neuropathic eruptions also an annular form was acquired by peripheral extension, the same as in the case of the ringworm. This was the case in erythema annulatum. The ringed eruptions of syphilis might develop in either way. When the eruption began as a ring it could hardly be explained otherwise than as a neuropathic effect. Whether, when it began as a papule and afterward became a ring through healing at the center and advancing at its circumference, it was due to a superficial growth and extension of the parasitic element of the disease, was a question not easily answered. Usually, however, in the annular syphilidernas the ring was not complete. At some point of the periphery there was apt to be a clear or re-entrant portion. Psoriasis was often ring-formed, and apparently might be produced in either way. Usually it was developed from an orbicular patch. But various curvilinear or gyrate forms that sometimes seemed to occur primarily indicated the tendency to annular formation, and here and there a more or less perfect ring might be formed that was not due to healing of the center of a patch. This tendency seemed to imply one argument in favor of the neuropathic origin of this disease as against the parasitic theory. Finally, eczema sometimes showed in places a tendency to form rings with more or less clear interiors. It was mostly in the parasitic forms that this occurred, but a similar effect might be due to nerve influence. The writer of the paper had omitted to refer to lupus erythematosus, in which the eruption was sometimes annular. There the ring form, though in a disease pretty certainly neuropathic, was produced by peripheral extension.

Dr. John A. Fowyer stated that when the students in his clinics saw a ringed eruption their first impression generally was that it was ringworm, before the fact was brought to their attention that many other cutaneous diseases assumed the same outlines. The annular syphilidernas, especially about the face and neck in a subject affected with seborrhoeic eczema, very
frequently closely resembled tinea circinata. Ringworm, on
the other hand, did not always take on an annular form, but
sometimes occurred in the form of scaly patches like eczema.
In exceptional instances, lupus erythematosus, as had been
stated by Dr. Bronson, lupus vulgaris, and even some varieties
of cutaneous cancer assumed circular outlines. Impetigo her-
petiformis, an exceedingly rare disease, also occurred in
the form of rings. He agreed with Dr. Bronson that the majority
of ringed eruptions were parasitic; the peripheral extension of
the eruption was due to the fact that the parasite in its growth
sought new soil, while the inflammatory reaction disappeared
as the parasite invaded new territory. The ringed forms of
erythema, on the contrary, were probably owing to a vascular
disturbance brought about by the nervous mechanism governing
limited areas.

The President asked whether the specific germs of inflam-
mnation might not be admitted as a third factor in addition to
the two enumerated by Dr. Bronson. He cited Dr. E. W. Tay-
lor, who had stated that possibly streptococci and staphylo-
cocci had a good deal to do with infiltrations and ulcerations of
syphilis; if this was the case, why not with other skin diseases,
such as those that had been discussed?

Dr. Jackson stated that this was an age of micro-organisms.
There were some dermatologists who, whenever they saw a
ringed eruption, always looked for a parasite. He was not yet
prepared to accept the parasitic theory of most ringed erup-
tions, as proof of such origin was wanting. He had not men-
tioned lupus erythematosus and epidermolysis, because they were
uncommon. In regard to the president's question, he knew the
theory existed that parasites caused these changes, and some
authorities thought that a great many of the ring lesions of
syphilis were not due to the syphilis itself, but to some micro-
organism. It was best to be slow in accepting such radical
views.

**Book Notices.**

*Degeneration.* By Max Nordau. Translated from the Sec-
ond Edition of the German Work. New York: D. Apple-

At the present day, when our theaters are presenting plays
in which adultery, seduction, bastardy, opium-eating, and fornica-
tion are prominent features in the career of some of the
dramatis personae; when "living pictures" are constituted by
women whose features proclaim the harlot, and whose fat,
bloated abdomens, atrophied calves, and adipose thighs and
arms violate the fundamental principles of anatomical beauty;
when the ballet caters to pornographic instincts by its coarse
suggestiveness; when books by vagueness or open reference ex-
plot the beneficence of salaciousness—the advent of such a
work as this is a matter for rejoicing. The earnestness with
which the author has written, and his care to present plenti-
ful data to sustain his thesis, are sure to make his book receive
wide attention and much discussion.

A pupil of Lombroso, to whom the book is dedicated, Nor-
dau justly accords to Moré credit for the introduction of the
notion of degeneration, and he calls attention to the fact that
degenerates are not always criminals, prostitutes, anarchists,
and pronounced lunatics, but are often authors and artists.
Some of these degenerates have come into extraordinary promi-
nence in literature, music, and painting, and are revered as
creators of new arts and heralds of future artistic canons. As
the powerful suggestions of books and works of art on the
masses produce the ideals an age entertains of morality and
beauty, the productions of degenerates are likely to have a
permanent influence on youth and create a sect of mental and
moral agonizers.

But in this latter concept it seems that the author is at
fault. Lincoln, with ready aphorism, said something to the
effect that it was possible to "food" all the people sometimes
and some of the people all the time, but that no one could fool
all the people all the time; so it is unlikely that any of the
prophets of new artistic or literary departures will be able to do
more than raise up a limited and temporary following, though
there is no doubt that their following will be among those im-
pressibles that might have been led by a good rather than a bad
example.

Throughout, Dr. Nordau attempts a scientific criticism that
does not base its deductions upon the purely accidental, capri-
cious, and variable emotions awakened by a work of art, a
piece of music, or a book, emotions that depend upon the tem-
perrment and mood of the individual, rather than upon the
psycho-physiological elements from which the work sprang.
He is no iconoclast, seeking to destroy the true ideals, but a
Moses who would break up the clay that constitutes the high-
worshiped by the multitudes.

In his first section he considers what is embodied by the
phrase *fin de siécle,* and this is the weakest part of the book.
He objects to the simile that a century is a kind of living being,
and calls this a childish anthropomorphism or zoomorphism.
But since the dawn of literature the idealization of time as a
sentient being has existed, and if a year may be considered as
partaking of the characteristics of human life, having its birth,
growth, and death, why not a century? It seems as if this
chapter might have been advantageously omitted, and the sec-
ond chapter, on the symptoms, in which the author Launches
his thunderbolts at the vagaries of *coiffure* and *mode,* is not to
be taken seriously. It may be considered that disconnected
and antithetical effects in house-furnishing are the consequences
of crude or imperfectly developed taste rather than manifesta-
tions of mental aberration or degeneration. And it seems too
swarming to assert that an artist arranges, à la Bayreuth, a con-
cert in a totally darkened hall, and thus "delights those of the
audience who find opportunity, by happily chosen juxtaposi-
tions, to augment their musical sensations by hidden enjoy-
ment of another sort." Not only does the Philistine regard
these as passing fashions, but the psychiatrist is not likely to
look upon them much more seriously, even if he accepts Moré's
definition of degeneracy: "A morbid deviation from an ori-
ginal type. This deviation, even if at the outset it was ever so
slight, contained transmissible elements of such a nature that
any one bearing in him the germs becomes more and more in-
capable of fulfilling his functions in the world; and mental
progress, already checked in his own person, finds itself men-
caced also in his descendants."

After reviewing the physical stigmata of degeneration, the
mental stigmata of lack of sense of morality, of right and
wrong, of unbounded egotism, emotionalism, mysticism, and
impulsiveness are referred to. "The degenerate finds that it
is easier and more convenient to allow his brain centers to pro-
duce semi-lucid, nebulously blurred ideas and inchoate embry-
one ideas, and to surrender himself to the perpetual obses-
sion of a boundless, aimless, and shoreless stream of fugitive
ideas, and he rarely arouses himself to the painful attempt
to check or counteract the capricious and, as a rule, merely me-
canical association of ideas and succession of images, and bring
under discipline the disorderly tumult of his fluid presentations.
On the contrary, he rejoices in his faculty of imagination,
which he contrasts with the insipidity of the Philistine, and de-

votes himself with predilection to all sorts of unlicensed pursuits permitted by the unshackled vagabondage of his mind; while he can not endure well-ordered civil occupations requiring attention and constant heed to reality." This is an excellent portrait of the degenerate, as will be recognized by every physician who has had much to do with the mentally affected. Among the peculiarities that are manifested by degenerates are tormenting doubts, a search for inexcusable first causes of phenomena, a yearning to expose the riddle of the universe, to search for the philosopher's stone, to square the circle, or to discover perpetual motion. There is an incapacity for adaptation to existing circumstances, a rebellion against conditions and views of things that are felt to be painful because they impose the duty of self-control that is difficult or impossible because of organic weakness of will. The degenerate would improve the world and devise plans for making mankind happy.

Every psychiatrist knows the truth of Legrain's dictum that the degenerate may be a genius, for a badly balanced mind is capable of the highest of conceits, while it also displays traits of meanness and pittiness that are all the more striking because they coexist with the most brilliant qualities. Nordau says: Let us imagine a Schopenhauer who had written no astounding books, and we should have before us only a repressive lusus nature, whose morals would necessarily exclude him from all respectable society, and whose fixed idea that he was a victim of persecution would point him out as a subject for a madhouse. Unlike Lombroso, who has said that highly gifted degenerates are an active force in the progress of mankind, Nordau considers that they corrupt, delude, and exercise a baneful influence, leading men along paths to new goals which are abysses or waste places.

Lombroso has said that if they are painters their predominant attribute will be the color sense. And the curious style of some recent painters becomes intelligible in view of the researches of Charcot and his pupils into the visual derangements in degeneration and hysteria.

The etiology of degeneration is the addiction to narcotics and stimulants, such as alcoholic drinks, tobacco, opium, cannabis indica, and arsenic, the use of tainted foods, the absorption of organic poisons, such as those of paludal fever, syphilis, tuberculosis, and goitre. Then the effect of a large town on the human organism in consequence of the inhalation of organic detritus, the eating of stale, adulterated, or contaminated food, and the constant nervous excitement diminish the vital powers. Hysteria is often due to fatigue, and there is evidence that shows degeneration may be due to the same cause. Our simplest activities involve an effort of the nervous system and a wearing of tissues; every civilized man performs to-day from five to twenty five times as much work as was required of a man half a century ago. New discoveries and progress have taken civilized humanity by surprise, so that it has had no time to adapt itself to its changed conditions of life.

The author then considers mysticism as a principal characteristic of degeneration. The premonachite fall is reviewed, and its evolution into symbolism, a cult that professes to understand a word (or series of words) expressing, instead of a fact of the external world or of conscious thought, an ambiguous glimmer of an idea that does not force the reader to think, but allows him to dream, and hence brings about no intellectual processes, but only moods. Numerous quotations are given from the writings of symbolists that show types of degeneration.

It is impossible within the compass of this review to give any good idea of the immense amount of reading the author has done, or of his care to substantiate his assertions by facts. His conclusions must be read to be appreciated.

The book is always interesting, and, while occasionally the author may seem extravagant in statement, such slips are rare. The translation is satisfactory; so good, in fact, that we do not appreciate the reason for omitting the translator's name. On page 109, "typhus" should read typhoid. On page 310 the expressions "wagon-lit" and "sleeping" [car omitted] are transposed.

There is no doubt that this work deserves as much attention in this country as it has received in Germany and England.

This volume is devoted to the diseases of the uropoietic system. Dr. Francis Delafield is the author of the first section, on diseases of the kidneys. He briefly reviews the anatomy of these organs, gives several of the better-known classifications of the nephropathies, and calls attention to the fact that the tendency of authors has been to look at these diseases from two points of view, that of the symptoms and that of the lesions. He shows that a classification based on the part involved, while anatomically correct, is clinically insufficient, and he advocates a classification according to the nature of the morbid processes. The quantity, specific gravity, and constituents of the urine are briefly reviewed. The factors causing albuminuria are mentioned, and the conditions in which there may be albuminuria without renal disease are described. It is a surprise to find no reference to the investigations of Bouchard, Hiler, and others in the section on uremia, for the symptoms of which the author thinks there is no satisfactory way to account. Bouchard seems to have proved conclusively that uremia is a complex poisoning to which, in unequal proportions, all the poisons introduced normally into the organism or found therein physiologically contribute. And his experiments seem to explain the anomalies that apparently puzzle Dr. Delafield and cause him to take his agnostic position on this subject, which is far from being a twentieth-century conception. The rest of this chapter is a very interesting exposition of the medical diseases of the kidney, the author manifesting a conservative position regarding all most points. Thus, in the section on purpuric ecchymosis four theories regarding its etiology are referred to, but to none of them does the author commit himself.
Mr. Reginald Harrison is the author of the chapters on surgical diseases of the kidneys and the bladder, and the accomplished surgeon of St. Peter's Hospital has performed his work in his usual thorough manner. He advances good reasons for accepting the colloid theory in regard to the formation of renal calculi, and he prefers the lumbar operation for their removal. This author reports some interesting cases of foreign bodies in the bladder, and he recommends the use of the electric cystoscope for exploration in these and other vesical diseases. The advantages of lithotripsy and perineal and suprapubic cystotomy, as well as the particular indications for each of these operations, are judiciously and fully discussed.

The chapters on diseases of the prostate and of the male urethra are by Dr. G. Frank Lydston. His review of the question of prostatic hypertrophy is one of the best articles on that important topic that we have read, and this is also true of the article on strictures. The author properly in-dorses Otis's method of internal urethroscopy as the simplest, safest, and most successful way of treatment of penile strictures.

Mr. E. Hurry Fenwick is the author of the chapter on diseases of the urethra, in which he states it was deemed expedient to revert to the old-fashioned custom of raising a suspicion to the rank of a disease. Hämaturia, pyuria, accidental albuminuria, cystinuria, phos-phaturia, oxaluria, polyuria, and chyluria are thoroughly discussed.

That Dr. Howard A. Kelly is the author of the chapter on diseases of the female bladder and urethra is sufficient evidence of the thorough manner in which those maladies are considered.

The articles in this volume are well written and deserve general attention.

This volume is virtually a reprint of the Cartwright Lectures for 1894, that were originally published in the Medical Record, and are now reissued in compliance with many requests for their publication in a more convenient and accessible form.

These lectures consider the many questions concerned in the digestion and utilization of the proteid food-stuffs, with particular reference to the chemical and physiological character of the products formed, and the general features of proteolysis.

The volume merits careful study, and gives a clear idea of the digestive process as applied to the essential food-stuffs.

Materia Medica and Therapeutics for Physicians and Students. By John B. Biddle, M. D., Late Professor of Materia Medica and General Therapeutics in the Jefferson Medical College, Philadelphia. Thirteenth Edition, revised, rearranged, and enlarged. With special reference to Therapeutics, Toxicology, the Physiological Action of Medicines, and containing all the Preparations and Remedies described in the United States Pharmacopoeia of 1890, to which the work has been made to conform. By Clement Biddle, M. D., Medical Corps, United States Navy. With Numerous Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1895. Pp. 5 to 714. [Price, $4.]

The editor states that in this edition he has preserved the same order that was followed in preceding editions in the consideration of each drug or remedy: and as this edition is tend to include all the articles and preparations considered in the United States Pharmacopoeia of 1890, a number of drugs that were made official by that revision have been added to the list formerly described in this work, also a number of drugs and preparations have been dropped. The editor has added a number of unofficial drugs that are more or less generally employed. These changes have added some fifteen pages to the work proper, and about sixty pages to the appendix.

The labor of revision has been carefully performed, and the work is fully up to date. Perhaps it would have been better to prefix "diphtheria" to "antitoxine," as there are tetanus and other antitoxines. By the way, tetanus antitoxine is not mentioned, and there is no reference to thyroid extract. Orzine and piperazine have so signally failed to fulfill the allegations that were made for them that their consideration might be omitted from future editions.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, A. M., M. D.

(Continued from page 286.)

The Retinal Changes in General Sepsis.—Herrneiser (Kl. Monat. f. Aug., May, 1894) asserts that in patients who have died of septic poisoning, preparations of the retina or choroid of these eyes will show the presence of bacteria. In the cases examined by him he has found these changes in 32.6 per cent. valuable for diagnostic purposes though not of prognostic value. His experience has taught him that a considerable number of these patients who showed very marked retinal septic changes recovered entirely and with normal eyes. Hemorrhages occur in these eyes shortly after the general infection has set in. The author believes that metastatic inflammation in the eye and retinitis sepsica are simply different degrees of intensity of the same process. He makes a distinction between retinal changes seen in septic processes and metastatic retinoclorodiritis, the latter being always due to an invasion of bacteria.

Is the Origin of Lenticonus to be sought in an Anomalous Condition of the Posterior Surface of the Lens?—Müller (Kl. Monat. f. Aug., June, 1894) is of the opinion that there are lenses which refract light to a different degree in different segments, and that the difference in refrangibility varies from a few dioptres to twenty-four dioptres. In those cases in which posterior polar cutaract or some other congenital opacity in the neighborhood of the posterior surface of the lens exists, the cause of the lenticonus must be regarded as congenital. In other cases the anterior surface of the lens is conical. In another series of cases abnormal shape of the nucleus is the cause. Müller advises that the name "lenticonus" be dropped, and that instead we employ the term "lens with double face."

A Contribution to the Knowledge of Traumatic Scleral Staphyloma.—Duffing (Archiv für Ophthalm., xi, 2) gives the following results of his examination of an eye that had been injured by a double perforating wound. The scleral staphyloma was developed in the upper equatorial region and involved all the coats of the eye in this region. This traumatic staphyloma of the upper half of the eyeball consisted of entirely newly formed tissue furnished by the sclera, and this new tissue was as thick as the sclera. The fibers of the newly formed tissue have the same direction as those of the normal sclera, and merge imperceptibly with those of the normal sclera.

The Deposit of Rust in the Cornea.—Gruber (Arch. für Ophthalm., xi, 2) gives the following results of his investigations.

1. Particles of iron which have penetrated the cornea behave very differently at times according to their chemical qualities. Metallic iron and ferrum oxydulatum in their chemical relations to be regarded as different, but oxide of ferrum is indifferent. Mixtures of both vary in their chemical irritating qualities according as the oxydulatum overbalances the oxide. The deposit of rust left in the cornea by a foreign bit of iron which has been extracted consists merely of hydrated oxide of iron, and chemically considered is harmless.

2. Even when the foreign particle has not entirely perforated the cornea, there is often a deposit of oxide of iron on the membrane of Descemet.

3. The deposit of rust outside of the foreign body follows very rapidly, so that within five minutes the deposit of the rust-ring begins.

4. The corneal epithelium exhibits great powers of resistance against the entrance of oxide of iron; very much greater than the substantia propria of the cornea.

Contribution to our Knowledge of Concentric Limitation of the Visual Field.—Groenow (Arch. für Ophthalm., xi, 2) gives the following results of his investigations into the occurrence and nature of paradoxical dilatation of the visual field:

1. The extension of the visual field which has been concentrically narrowed in consequence of functional lesions depends within certain limits upon the degree of tension of the accommodation under which the visual field is measured. It is wider by relaxation of the accommodation than by tension of the same. The concentrically narrowed field is influenced by relaxation of the accommodation in exactly the opposite way from the normal field.

2. The paradoxical widening of the field can only be distinctly shown when the field has a more marked concentric narrowing.

3. The paradoxical widening of the field may best be demonstrated by measuring the field once while the patient accommodates for near point, and once in complete relaxation of the accommodation by the interposition of a proper convex glass. Partial relaxation of the accommodation, as a rule, is not sufficient.

4. Paradoxical widening of the field may be demonstrated in asteniasis retinae, copioptis hysteria, hemeralopia, spasmodic myopia, traumatic neuroses, tobacco anthyposis, etc.

5. The paradoxical widening of the field in accommodation for the far point disappears and its place is taken by the physiological widening of the field.

Unilateral Reflex Iridoplegia.—Heddens (Arch. of Ophthal., xxiii, 1 and 2) refers to the five hitherto reported cases of reflex iridoplegia with a view to locating the lesion and defining the cause. If, as is usually supposed, the sphincter nucleus receives impressions on the one hand from centripetal pupillary fibers reaching it from both sides, and on the other hand from the accommodation nucleus of the same side, it is difficult to understand how with an affection of the sphincter nucleus the transmission of the accommodative impulse to the pupil may be possible while the transmission of the light stimuli is interrupted. Since in all the cases of unilateral reflex iridoplegia
hitherto published the accommodation was intact, it seems natural to suppose a mechanical influence of the accommodative branch of the third nerve on the contraction of the pupil. Perlia's well-known scheme of the nuclei of the third and fourth nerves suggests another possible explanation—viz., that the nuclei do not stand in direct connection with each other, so that the sphincter nuclei cannot be irritated by the accommodative nucleus, but that the iris branch of the third nerve is composed of two roots, one from the sphincter nuclei and one from the accommodative nucleus. The supposition of a fascicular instead of a nuclear affection would be acceptable to those who believe that the third nerve of one side arises in great part from the nucleus of the same side, and in lesser part from the nucleus of the opposite side. According to this explanation, the cause of the unilateral reflex iridoplegia may lie entirely in the centrifugal portion of the reflex arc for the light reaction. Then, there being a lesion of the branch from the sphincter nucleus, the reaction of the pupils to light would be the same as when the third nerve of this side was totally paralyzed. The dilated pupil would not respond to light directly or consensually; the other pupil would appear somewhat narrowed, and would react consensually more directly than directly, since the pupil of the paralyzed eye allows a greater amount of light to reach the retina.

The External Use of Quinine in Blennorrhoeic Ophthalmia.—Reich-Hollender (Arch. of Ophthol., xxii. 1 and 2) used a quinine lotion experimentally in an obstinate case of gonorrhoeal ophthalmia, and found that after the third day the discharge became innocuous, and within two weeks not a vestige of the inflammation remained. By making cultures he satisfied himself that the gonococcus Neisser was destroyed by a solution of quinine. He considers that the best way to employ quinine is in a solution containing hydrochloric acid. He believes it to be a specific in the rages of the gonococcus. He makes a solution of 8 parts of quinine, 3 of dilute hydrochloric acid, and 720 of distilled water, and applies it every hour.

Injury to the Eyes from a Heavy Charge of Electricity.—Sivers (Arch. of Ophthol., xxii. 1 and 2) reports an interesting case of a man, aged twenty-five years, who received a current of five hundred and fifty volts, which passed through his arm as it was held on a level with his face. The eyelashes and eyebrows were entirely burned off. The skin of the eyelids was blistered. The ocular conjunctiva looked as if it had been painted with a strong solution of silver nitrate. The cornea in each eye looked like ground glass. Vision was reduced to perception of light. The treatment consisted of thorough and frequent irrigation by very hot boiled water, and a few drops of pure castor oil were instilled after each washing. Four times a day a solution of two grains of atropine sulphate to the ounce of bichloride solution (1 to 5,000) was used. The eyes were kept constantly covered by aseptic dry cloths. On the second day the opaque portion of the cornea began to separate, and by the end of the third day the eschar had been thrown off entirely in one eye, and on the fourth day in the other eye, leaving behind a perfectly clear structure in each eye. Fifteen days after the accident an examination showed: R. E. 2/5; L. E. 2/5. Jaeger No. 1 at six inches. The ophthalmoscope revealed a normal fundus.

Paralysis of the Superior Rectus and its Bearing on the Theory of Muscular Insufficiency.—Dume (Arch. of Ophthol., xxii. 1 and 2), after discussing the subject of paralysis of the superior rectus and its relative frequency, states that no insufficiency of an ocular muscle should be considered or treated simply as an insufficiency; we should rather try to rectify the often complex causes which lie at the root of it. We should in every case of heterophoria first eliminate the effect of accommodative errors by correcting the refraction; then determine, by careful and repeated examinations of the diplopia and the tendency to deviation in the different parts of the field of fixation, whether the heterophoria is a concomitant one, or varies in a way to indicate muscular paralysis or spasm. When in this way we have found the cause of the condition and the muscle which is at fault, and are convinced that the condition itself is a stationary and not a variable one, we are ready to rectify the anomaly, provided it really seems to be worth rectifying.

A Critical Comparison of Leber's Theory of Detachment of the Retina with the Diffusion Theory.—Reichmann (Arch. of Ophthol., xxiii. 1 and 2) considers that there are several points in this subject which can not well be explained by the theory that shrinking of the vitreous ruptures the retina and then detaches it, which may all be explained by the diffusion theory. This theory also explains the reattachment, with restoration of function, which occurs in exceptional cases. The process of detachment, as explained by the diffusion theory, is analogous to the occurrence of oedema or transudation in other parts of the body. Detachment of the retina occurs more frequently in individuals disposed to oedema than in healthy individuals. A careful consideration of the diffusion process, which plays the chief rôle in the shrinking of the vitreous, enables us to recognize the shrinking as a collateral symptom and the rupture as secondary.

A Triple Rotary Variable Prism.—Jackson (Arch. of Ophthol., xxiii. 1 and 2) has devised a prism fitted to use in the ordinary trial frame. In this instrument the prisms are arranged so that the components increasing with the sine of the angle neutralize each other, and the components diminishing with the cosine of the angle are available for use. To effect this it is necessary that the rotary prisms start from the position in which they act together, producing their maximum effect, which must be exactly neutralized by an equivalent third prism. As the rotary prisms proceed from this position their effect diminishes with the cosine of the angle, and by so much leaves the third or fixed prism unneutralized to produce an increasing prismatic effect. This effect is at first very slight, but the increase is progressively more rapid until the rotary prisms have each passed through 90° and are made to neutralize each other. Continuing the movement of the rotary prisms, they begin to produce an effect in the same direction as the fixed prism, which effect increases more slowly until after passing through 180° the maximum effect of the rotary prism is added to that of the fixed prism. The delicacy of the instrument for producing slight prismatic effects may be judged by the fact that the rotary prisms must each be turned through 9° to produce the first quarter centrad of prismatic effect.

Sixty-six Magnet Operations, with Successful Extraction of Particles of Iron from the Interior of the Eye in Fifty-three Cases.—Hildebrand (Arch. of Ophthol., xxiii. 1 and 2) here gives in detail the results of sixty-six magnet operations, in sixteen of which good vision was preserved. In fifteen cases the foreign bodies were lodged in the anterior chamber, iris, or lens. The operations took a favorable course in all but one, where severe purulent inflammation had existed before the operation. In fifty-one cases the iron splinters lodged in the vitreous chamber. In thirteen no foreign body was extracted. Of the thirty-eight cases in which the foreign bodies had been extracted, the following results were obtained:

Two led to enucleation; seven to phthisis bulbi. Six were lost sight of. Seven preserved the shape of the eye. Sixteen yielded a good result, more or less good vision being permanently restored. Cases which on discharge had tolerably good sight, but soft eyes or notable turbidity of the vitreous, were
not counted among the successes, for these cases are apt to become worse later by detachment of the retina or shrinkage of the globe.

All the operations, except the first eight, were performed with a Hilger-Rohmstorff electro-magnet connected with a storage battery. The magnet should be introduced as near the foreign body as diagnosis and position permit; charring of the vitreous should be avoided.

The incision into the tumour of the eye should be meridional, and made with a narrow knife, after separation of the conjunctiva with a pair of scissors. Thin and pointed electrodes are to be avoided.

Whenever an iron particle in the interior of the eye is recognized with certainty, its extraction is indicated. Even those which seem firmly attached to the background, and cause neither irritation nor impairment of sight, are better out than in.

It is advisable to operate as soon as the presence of the foreign body can be ascertained. Even if it can not be seen or located, its removal should be attempted whenever it causes a severe inflammation. If it is impossible to locate the foreign body it is generally safer to wait until the media have cleared than to stir the vitreous extensively.

The diagnosis of the presence of a foreign body is of the greatest importance. The history of the injury, the instrument from which the piece flew off, will aid us considerably.

Air bubbles seen in the vitreous are a sure sign of the presence of a foreign body in the eye. If the vitreous is more cloudy in the lower part than in the upper, the patient should be examined in different positions of the head. The magnet itself is in some cases a serviceable means of localizing the foreign body. When passed over the sclera, no pain or tenderness is felt except when the electrode is in the immediate vicinity of the foreign body.

If a small wound of the conjunctiva has been produced by a foreign body, the wound should be examined with a platinum wire made aseptic by heat, in order to determine whether the sclera is perforated or not.

**Prognosis**—There are three hundred and twenty-two cases reported in literature in which the magnet has been introduced into the eye. In eighty the foreign body lodged in the anterior part, in the others in the vitreous.

Of the eighty cases, thirteen ended unfavorably on account of purulent inflammation which had set in before the operation. Seventy-seven cases yielded a perfect result.

In seventy-four of the two hundred and forty-eight cases in which the magnet was introduced into the vitreous, the foreign body was not found. In one hundred and seventy-four cases the particles of iron were extracted. Twenty-three of these, or thirteen per cent., led to phthisis bulbi. Twenty-six, or fifteen per cent., required subsequent excision. Of thirty-four cases the results could not be obtained. The remainder, ninety-one cases, or fifty-two per cent., gave satisfactory results—viz.: Twenty-nine cases, or sixteen per cent., retained the shape of the eye. Sixty-two patients, or thirty-six per cent., retained more or less vision.

**Three Cases of Tubercle of the Iris.**—Sandford (Ophthal. Rev., May, 1894) reports three cases of this nature. The first two were examples of iritic tuberculous deposits coincident with fresh lung trouble of a similar nature. The third case was one of primary iritic tuberculosis, the ciliary region, suspensory ligament, and apparently the lens itself being infiltrated by the tuberculous elements. The case occurred in a child, aged five years, of tuberculous parentage on both sides. There was no evidence of tuberculous mischief in any other organ. The tuberculous mass half filled the anterior chamber. The eye was enucleated and the patient was still living eight years later.

**Intracranial Abscess arising from Caries of the Sphenoidal Cells.**—Sanford (Ophthal. Rev., May, 1894) reports a case of this kind in which the abscess caused double optic neuritis and subsequent post-neuritis atrophy, with complete blindness, about twenty-seven years before the patient's death, at the age of seventy-eight years. The abscess had penetrated the left orbit, causing proptosis, and also the outer wall of the skull by erosion of the bone.

**A Rare Form of Intracocular Melanoma.**—Griffith (Ophthal. Rev., May, 1894) reports a case of some interest. The tumor was epithelial in nature and started in the tapetum nigrum of the retina. The ciliary body was not invaded, but merely displaced inward by the tumor pushing its way into the lymph space to the outer side of the ciliary muscle. He regarded the case as an instance of a melanoma springing from the retina, and conforming rather to the type of carcinoma than sarcoma.

**Primary Melanotic Sarcoma of the Eyelid, with Report of a Case.**—Zimmerman (Ophthal. Rev., June, 1894) reports a case of this nature, occurring in a sailor, aged fifty years, with an exceptionally good personal history. Ten months before he came, he had noticed a swelling in the left upper lid, near the external canthus. There was slight itching, but no pain until shortly before the author saw him. The growth had been extremely slow until about a month before, but had since been rapid. There had been no hemorrhage. The outer half of the left upper lid was the seat of a tumor of a dull bluish color, a centimetre long, oval, and of moderate height. It reached to the lid margin, but did not involve the conjunctiva. The skin was adherent and slightly nodular, but not eroded. There was no tenderness. The tumor was excised with a margin of healthy tissue, some points of doubtful character being destroyed by the galvano-cautery. The deformity was subsequently corrected by a plastic operation, which involved some change in the shape of the defect, and its closure by means of a sliding flap from the temple. Healing was prompt and uninterrupted. Eighteen months after the operation the conditions remained unchanged, and there had been no return. The tumor was found to be a melanotic spindle-celled sarcoma, incompletely encapsulated. The conjunctiva was not involved or distinctly changed, and the muscular tissue of the lid was not affected. The point of origin remained in doubt, but was probably within the Meibomian glands.

**Optic Neuritis in its Relation to Cerebral Tumor and Trephining.**—Taylor (Ophthal. Rev., June, 1894) in this paper alludes to the fact to which Horsley had some time before called attention—namely, the subsidence of optic neuritis after operation undertaken with a view to the removal of cerebral tumor, even when the tumor was not removed. Similar observations had been recorded by Bruns and Erb, and in this paper it was intended to emphasize the fact that not only in cases in which a tumor was removed from the brain did the optic neuritis subside and the discs resume a normal appearance, but even in other cases of tumor in which the skull was opened, but the tumor not removed or interfered with further, a similar subsidence of the swelling of the discs took place. He urges, in conclusion, that even while freely admitting that a large cerebral tumor might be present without producing optic neuritis, and that optic neuritis might be present without cerebral tumor, there were yet certain cases of intracranial tumor in which the pressure inside the skull was the effective agent in producing what was known as optic neuritis.

**Partial Suppression of the Employment of Collyria.**—Wecker (Ann. d'oev., June, 1894) lays down the following rules for the treatment of simple ulcers of the cornea: 1. Careful disinfection of the lids, especially the ciliary margins and the lashes. 2. Curetting the ulcers with careful irrigation. 3. Sub-
conjunctival injection in the vicinity of the infiltrated parts of a few drops of a solution of sublimate (1 to 1,000). 4. Rigorous application of the oculating flap without the employment of any collyrium.

Considerations on the Cortical Visual Center.—Violet (Rec. d'ophtal., June, 1894) reports two cases which seem to confirm the theory that a circumscribed lesion of the internal surface of the occipital lobe may cause persistent hemianopsia, and to justify the localization of the visual center of perception in the three convolutions of this internal surface. The cortical zone in which the visual fibers terminate is not as circumscribed as hitherto believed by Henschen, who locates it exclusively in the calcarine fissure.

Simple Muscular Advancement in Cases of Moderate Strabismus.—Motaia (Rec. d'ophtal., June, 1894) recommends this operation in the following cases: 1. In parietic squints of from five to fifteen degrees. 2. In the squint of very young children. 3. In the unsatisfactory results of previous tenotomies, when the persistent deviation is not more than twelve degrees and resists all optical means for its relief. 4. In compound squint when the superior deviation is not cured after the correction of the undue convergence. 5. In muscular insufficiency, except in myopes.

The Cerebral Optic Centers.—Henschen (Rec. gén. d'ophtal., Aug. 31, 1894) draws the following conclusions from his observations: 1. Hemianopsia can only exist when there is a lesion of the fasciculus of the occipital optic tract or of the calcarine cortex. 2. A cortical lesion of the parietal lobe can give rise to hemianopsia only when it touches the visual fasciculus in the lower portion of the optic radiation. 3. The optical center is confined to the cortex of the calcarine fissure. 4. Both fasciculi, the crossed and the direct, are present in the cortex of the calcarine fissure. 5. The cortical macula lutea is to be found in the anterior part of the calcarine fissure. 6. The central portion of the optical center is not found in the cuneus. 7. In the so-called cerebral retina the macula lutea is situated the most anteriorly, and the peripheral field farther backward in the horizontal meridian; the upper lip corresponds to the dorsal portion of the retina of the ocular lobe. The two fasciculi, crossed and direct, are represented in this surface, and their elements are probably located side by side. The cerebral retina is at the same time a retina for the perception of colors. 8. The two halves of the macula lutea are often represented in the two hemispheres.

The Inclinometer in Ophthalmology.—Prince (Ophthal. Rec., July, 1894) has devised an instrument which consists of a thin, circular metal plate, one millimetre in thickness and thirty-seven millimetres in width, with a central aperture. The periphery is so graduated that the superior or zenith point will indicate every possible inclination of the diameter, the situation of which is shown by a strong white line. The two sides are graduated respectively to indicate the inclination of the diameter from the horizontal and vertical lines, the former for determining the axis in astigmatism, and the latter for such purposes as require the zero point to be in the vertical plane. In the practice of retinoscopy the inclinometer is rotated in the trial cell until the diameter is seen to correspond with the inclination of the shadow, the degree of which is to be found at the zenith point of the instrument. Accuracy is facilitated by employing a small source of illumination, best furnished by a one-centimetre aperture in a screen surrounding a Willkonsch gas burner. The light is placed close to and to the left of the observer, and reflected by means of a small plane mirror into the eye of the patient, who sits at the distance of a metre. The instrument is found to be convenient for determining the inclination of the axis of a trial cylinder. It facilitates the determination of the inclination of the principal meridians rendered apparent by the elongated image of a small circular object. The patient places the diameter parallel with the long diameter of the distorted image, when the pendulum or zenith will indicate the inclination of one principal meridian. The apparent inclination of a vertical object, due to paralysis of an oblique muscle, is denoted by the corresponding inclination of the diameter as seen by the unaffected eye.

A New Operation for Trichiasis and Distichia.—Watson (Ophthal. Rec., July, 1894) has devised an operation which consists in forming a bridge by incisions parallel to one another and to the margin of the lid, including in its substance the whole of the faulty eyelashes, a "buttonhole" lying horizontally above the margin of the lid thus formed. Into this "buttonhole" a "button," marked out in the skin immediately above it by a semilunar incision, is turned and fixed in situ by sutures. The result is to place a band of skin at the margin of the eyelid, and by this means the transplanted eyelashes are quite removed from the cornes.

New Operation for Distichia.—Germaix (Rec. d'ophtal., July, 1894) recommends the following method of operating: 1. Dissect the lid vertically into two laminae, the anterior one containing the hair bulbs, until the lower bulbs become visible. 2. Cauterize the lower hair bulbs with the galvano-cautery. 3. Continue the vertical dissection until the tarsus is laid bare for a distance of six or seven millimetres. 4. Excise a mucocutaneous palpebral flap, crescentic in shape, so as to uncover the suspensory ligament of the lid. 5. Introduce as many sutures as may be necessary through the suspensory ligament, and embracing in folds or loops the ciliary margin of the lid. The sutures are then to be tied, and the superior edge of the ciliary margin brought in conjunction with the upper part of the lid.

Ocular Gymnastics.—Hobby (Amer. Jour. of Ophthal., June, 1894) recommends muscular exercise and training in the treatment of strabismus and heterophoria. The system employed is to produce successive contractions of the muscle to be exercised, for a time short of extreme fatigue, from thirty to a hundred contractions at first, increasing the number in accordance with the ability of the patient to bear the work. Exercise of the ciliary muscle can be secured in a similar manner, by requiring the patient to look at a distant object, then at one close by, using small objects and being careful to secure accommodation each time before changing. Exercise in co-ordination can be obtained by using both eyes first on a distant object, then on a near one, using the same care to secure perfect accommodation before change, and repeating the changes as frequently as perfect accommodation will allow. Co-ordination can be practiced at different distances and angles, and it is well for the patient to wear full correction of any refractive error while practicing accommodation or co-ordination.

Researches into the Secretory Nerves of the Lacrymal Gland.—Topiachos (Arch. d'ophtal, July, 1894) draws the following conclusions from his anatomical investigations: 1. The idea that the facial nerve is the secretory nerve of the lacrymal gland is not confirmed. 2. The secretory filaments in the lacrymal and subcutaneous malar nerves, in their intracranial course, run in the trunk of the trifacial, and they probably participate in the augmented secretion of the tears which is provoked in a reflex way and under the influence of psychical emotions. 3. The normal and continuous secretion of the tears can not be considered as the sole result of a reflex coming from the excitation of the anterior part of the eyelid, and does not depend on the secretory filaments of the lacrymal and subcutaneous malar nerves. 4. The cerebral sympathetic may be regarded as the secretory nerve of the lacrymal gland, under the
influence of which the normal and continuous secretion of tears goes on. 5. The facts relating to the paralytic secretion of tears and their qualitative difference obtained by irritation of the lacrymal branch of the cervical sympathetic may well be questioned.

Amyloid Degeneration of the Conjunctiva.—Kruch and Funagalli (Ann. d'oc., July, 1894) draw the following conclusions from their investigations: 1. Amyloid degeneration of the conjunctiva may be entirely independent of the various processes of inflammation which may have preceded it in the conjunctiva. 2. The degeneration exists as a simple local process, without any connection with the general condition of the patient. 3. Even the merely partial excision of the degenerated tissue improves the local conditions and may lead to a cure. 4. The elements of the subconjunctival connective tissue contribute in great part to the production of the amylod substance. 5. The vessels do not represent the point of origin of the degeneration. 6. In the degenerated tissue are found two microbes with the characteristic signs of chronic inflammation.

Considerations on the Cortical Visual Center, based on Two Cases of Cortical Hemianopia with Autopsies.—Viallet (Arch. d'ophthal., July, 1894) reports the results of the clinical and post-mortem study of two cases of hemianopia. They seem to prove that a circumscribed lesion of the internal surface of the occipital lobe may cause persistent hemianopia and justify us in placing the center of visual perception in the three convolutions of this internal surface. The cortical zone into which the visual fibers enter is not as circumscribed as represented by Henschel, who confines it to the calcarine fissure. It really comprehends the entire internal surface of the occipital lobe, including the three convolutions of the cuneus and of the lingual and fusiform lobes. (To be concluded.)

Miscellany.

The Diagnosis of Acute Perimeningitis.—In the Journal des praticiens for March 16th there is an article on this subject in which the writer remarks that this disease is rare, and that few cases have been known previous to the one observed by M. Theslier.

Acute perimeningitis is an inflammation of the cellular fatty tissue around the cerebral dura. Its evolution is sometimes acute, spontaneous, with no appreciable pathogenic cause, and sometimes secondary, with cellular-muscular inflammation near the spinal column. The symptoms resemble those of inflammation of the medullary meninges. It begins with sharp pains, with alternate remissions and exacerbations, in the legs and along the spine, and they are accompanied by stiffness of the limbs or of the neck. At the same time there is febrile movement with constipation. Subsequently there are pains in the abdomen and in the lumbar region, also in the legs. During the suppurating period, when the spinal canal is invaded with pus, the disease becomes infectious; sometimes paralysis sets in, and death takes place in a short time. In this evolution the meningitic symptoms may fail to show themselves, and the diagnosis is consequently rendered more difficult.

The idea of cerebral meningitis, however, may be dismissed in the absence of the meningitic tripod, of ocular complications, and of the typical course of the temperature. Cerebro-spinal meningitis is epidemic and associated with infectious localizations in the lungs and in the heart, and its characteristics are distinct from those of acute perimeningitis. In the diagnosis of spinal meningitis great difficulties often arise, although in the beginning the early development of paralysis is a symptom of the disease. If it appears later on, there is reason to believe that it is a question of acute perimeningitis.

Perimeningitis, says the writer, may be confounded with typhoid fever, osteomyelitis, and rheumatism. For this reason, in the analysis of the symptoms, we should bear in mind that perimeningitis shows three different types in the beginning: A subacute type, with violent invasion, chills, headache, and renal pains; an acute type, the first symptoms of which resemble those of lumbago, and which is accompanied by insomnia, pains, cramps, and febrile movements; and the third type, which is slow, developing silently for several months before the symptoms appear.

The treatment of acute perimeningitis in the beginning is the simple expectant method, and, when it is possible, operative opening of the spinal canal.

The Pulse in Clinical Surgery.—The Revue internationale de médecine et de chirurgie pratiques for March 10th contains a review of a work by M. François Bertonnier on this subject. In this interesting work, says the writer, the author first recalls M'jee's statement as follows: "The pulse is the sensation of sudden swelling felt by the finger which palpates an artery. The blood-vessels that allows itself to be depressed becomes suddenly hard each time that a systole of the heart increases the arterial tension." Bertonnier then considers this physiological phenomenon with regard to its frequency, its power, and its rhythm. In two chapters he explains the connection between the pulse and the temperature, also the usefulness of examining the pulse in cases of severe hemorrhage. His principal conclusions are the following: 1. The discordance of the two curves, that of the temperature and that of the pulse, is often an indication of a serious condition. 2. In grave hemorrhage the great depression of the pulse that accompanies it has sufficed occasionally to indicate the true diagnosis. 3. In traumatic shock or that following an operation the degree of slenderness, of frequency, and of irregularity of the pulse will be the most exact measure of the violence of the shock and of the patient's vital resistance. 4. In traumatic cranio-cerebral lesions extreme slowness of the pulse is a never-varying sign of concussion, of contusion, or of cerebral compression. Eventually, its acceleration with elevation of temperature is a sign of meningo-encephalitis. 5. The pulse should often be a guide in surgical interference in traumatic or inflammatory affections of the abdomen. 6. The absence of arterial pulsation at the extremity of a member is a very important sign and calls for a prompt determination. Finally, the pulse, under the influence of chloroform, by its irregularity, intermitence, and arrhythmia, indicates, even better than auscultation of the heart, that the valvular lesions are badly compensated for, and that there is danger in the administration of chloroform.

The New York Academy of Medicine.—At the last general meeting, on Thursday evening, the 4th inst., one of the special orders was to be the presentation of a portrait of the late Dr. Valentine Mott. The following papers were to be read: Experiences in the Production and Use of Diphtheria Antitoxine, by Dr. Hermann M. Biggs; The Technique of the Production of Diphtheria Antitoxine, by Dr. William H. Park; Experiences in the Use of Diphtheria Antitoxine for Immunization, by Dr. C. H. Peck; The Results of Autopsies on Persons Dying after Treatment with Diphtheria Antitoxine, by Dr. George P. Biggs; The Anatomical Lesions found in Animals which have Died during the Process of Immunization, by Dr. Ira Van Gieson.
At the next meeting of the Section in General Surgery, on Monday evening, the 8th inst., a paper entitled Undescended Testis will be read by Dr. John B. Walker. Patients will be presented and pathological specimens, new instruments, and apparatus exhibited.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 9th inst., Dr. George Woolsey will read a paper on Some Considerations on Prostatectomy, and Dr. J. R. Haydon one entitled Double Castration for Hyper trophy of the Prostate, with the Report of a Case. Patients will be presented and new instruments and pathological specimens exhibited.

At the next meeting of the Section in Pediatrics, on Thursday evening, the 11th inst., the following papers will be read: What shall the General Practitioner do for Acute Otitis? by Dr. Edward B. Dench; Otitis in Young Children, by Dr. James E. H. Nichols; and The Cause and Prevention of Deafness, by Dr. Gorham Bacon.

The Treatment of Vomiting.—The Provincia medica for March 9th publishes an article in which the writer considers the question of the difficulty of controlling various kinds of vomiting. He recommends the following formulas, the first of which, according to Steffen, is useful in the vomiting of pregnancy: Distilled water, five ounces; tincture of iodine, twelve drops. A tablespoonful of this in half a glass of sweetened water is to be taken every two hours. The same author recommends the addition of a few milligrammes of morphiine hydrochloride to each spoonful, or an ounce of the distilled water may be replaced by an ounce of cherry laurel water. The Centralblatt für die gesamte Therapie, in one of its last numbers, recommends the two following formulas: 1. Chloroform, nine hundred grains; tincture of iodine, a hundred and twelve grains. Five drops of this are to be taken every night in a glass of Seltzer water. 2. Distilled water, three ounces and a quarter; cocaine hydrochloride, half a grain; antipyrine, fifteen grains. A teaspoonful may be taken every half hour.

The following procedure, says the writer, in which three solutions are used, has often been employed successfully: 1. Alcohol, a hundred and fifty grains; menthol, eight grains; tincture of nux vomica, thirty grains. 2. Tincture of iodine, a hundred and fifty grains. 3. Saturated chloroform water, three ounces. Every half hour, or every fifteen minutes if necessary, the patient should take a dessertspoonful of the chloroform water, which may be diluted with ice and Seltzer water, after having added ten drops of the first solution to it. If this is not sufficient two drops of the tincture of iodine may be added to each spoonful. Finally, if it is necessary, from two to three drops of a 1-in-50 solution of morphiine or cocaine may be added to these formulas. These two solutions are usually employed for subcutaneous injections. It is well to substitute occasionally for one of these medicaments from two to four drops of the ordinary solution of antipyrine for cutaneous injections, according to the following formula: Antipyrine, seventy-five grains; cocaine hydrochloride, two grains and a half; distilled water, a sufficient quantity to make ten cubic centimetres. If these different medicaments fail, says the writer, the physician may resort to the following therapeutic measure, which is very simple and has been successfully employed by M. Robin in serious cases: Apply a small blister to the pit of the stomach, also administer a small suppository containing a grain and a half of powdered cusco opium and a sufficient quantity of cacao butter once or twice during the twenty-four hours. The vomiting is very often arrested, even if it is the serious vomiting of typhoid fever. Sometimes, also, inhalations of oxygen are useful.

The Influence of Fatigue on the Auditory Functions.—The Provincia medica for March 16th contains an abstract of an article which was published in the Archivio italiano di otiologia for 1894. In order to study this question, says the writer, the author made examinations of twenty-four bicycle-riders after they had ridden thirty-two miles in two hours and a quarter. Two of the men complained of subjective noises only, while in nearly all of them the perception of sounds by aerial conduction was less marked than in the normal condition, and Rinne's experiment showed negative results. In the riders who were subjected to an examination with tuning-forks a slight diminution in the perception of loud sounds was ascertained. The only lesion noticed was a slight hyperaemia of the drum membrane.

The competitors were again examined after a rest of from two to seven hours, and in six of them the auditory power was found to be the same; in two it was not so good, and in the sixteen others it was better, the aerial perception having increased from a few centimetres to a metre and a half, and Rinne's experiments gave positive results. The men in whom the acceleration was the most marked, in whom, consequently, the hearing had undergone the greatest change, were those who had had little experience or training.

Physical fatigue, says the writer, evidently causes a temporary weakening of the auditory power. This fact demonstrates, besides, he says, that the effects produced by great physical exercise are not shown by muscular fatigue only, but they remotely affect the entire organism and especially the nervous system, and the special senses, on account of the delicacy of their functions, are more likely to reveal the effects.

The examiner shown by birds of passage after a long flight is a phenomenon of the same nature as that observed by the author in the examinations referred to.

A Syphilitic Lesion observed in a pre-Columbian Skull.—Dr. Albert S. Ashmead writes to us as follows: In the Bandelier collection, Metropolitan Museum, New York, there is a skull of a mummy, just being classified, from Pacha Cauca, on the Peruvian coast, near Lima. It was found twelve feet underground, and no other part of the skeleton was in a condition to be shipped. It is without doubt, according to Mr. Saville, the director, and Professor Putnam, who examined the specimen with me, pre-Columbian. In this burial place nothing modern, nothing post-Columbian has ever been found.

In the right supratemporal region of the skull, on the parieto-frontal suture, there is a mark of disease, almost eating through the bone; there is no doubt that the scalp had been removed, and what followed we may guess—it was found that the skull itself was affected, and the case was left alone. Evidently the man lived long enough to almost allow time to obliterate the mark of the surgeon's instrument. On the inside of the skull no mark of disease, except the extreme thinness of the tissue, strikes the observer. To my mind, this is an instance of syphilis in a pre-Columbian skull. The location of this lesion and the appearance of the diseased bone throughout are peculiarly syphilitic. I have seen such instances many times in Japan, on the living body, and once in a post-mortem examination in a yoshikirara (licensed prostitute).

Sudden Death in Consequence of a Urethral Injection of Cocaine.—In the Centralblatt für Chirurgie for March 16th we find an abstract of an account published in La Francia medica by M. Reclus, in a case in which sudden death followed an injection of about six drachms of a five-per-cent. solution of cocaine into the urethra. The urethral mucous membrane appeared to be quite intact, and the death was attributed to pronounced arterio-sclerosis and to the undue quantity of the drug employed.
Extreme Local Dilatation in the Treatment of Urethral Stricture and Its Allied Conditions.

By James P. Tuttle, M.D.,
Adjunct Professor of Surgery at the New York Polyclinic.

The many letters and personal inquiries I have received concerning the method of local dilatation in the treatment of urethral stricture and its allied conditions justify me in making to this section a supplementary report upon the subject. In 1891 I read before the American Association of Genito-urinary Surgeons a paper detailing my experiences with the method up to that time. In that paper I laid down the principles upon which the treatment is based, and stated that I had found, as a result of examinations of a considerable number of urethras in cadavers, the following:

1. A lessening in caliber of the membranous urethra, compared with that of the prostatic, averaging 3 ± millimeters.

2. A constriction at the anterior border of the bulbous portion, about at the point of attachment of the suspensory ligament, averaging nearly four millimeters. At this point the urethrometer nearly always gives a decided jump; it can usually be distended a size or two after passing here, and be drawn uninterruptedly to the next constriction.

3. A constriction of from one to three millimeters at the posterior border of the fossa navicularis, which, though not always present, was found in the large majority of cases.

4. The urethra could be distended at all points except the meatus to 50° F. without rupture.

5. A dilatation at the fossa navicularis in every case.

6. The size of the meatus bears no regular proportion to that of the urethra.

These observations were made upon healthy urethras, so far as I could discern, by dissection, and therefore we may conclude that these constrictions and dilatations are normal. Their existence, however, does not preclude the fact that we may have pathological contractions in these same locations, or that these same constrictions, unnoticed and unknown, so long as healthy, may become the starting point or protracting factor in intractable affections when once invaded by disease.

These views are in harmony with those of Sappey, who describes the urethra as a canal with four contractions and three dilatations. "Beginning at the neck of the bladder in a contraction, it is dilated in the prostatic portion; contracting in the membranous portion, it suddenly dilates into the bulbous pouch, which is about an inch and a half long; from this point forward it contracts for the space of an inch and a half to two inches and a half and to the extent of one to three millimeters in circumference; it maintains about this caliber from here outward to within three quarters of an inch of the end, where it dilates again to form the fossa navicularis, and ends at the meatus in a sudden more or less extensive contraction. These variations are no accidents of evolution or freaks of Nature, neither are the dilatations in one part due to contractions of another. They are natural anatomical constrictions, found alike in old and young, clearly designed for a wise purpose and demanding from us careful consideration and conservatism. No less are they necessary to perfect physiological functions than the nozzle to the fire hose or the curves in the pipes of our modern sanitary plumbing. That the nozzle may be too small for the hose and pump, or that some portion of the urethra may be disproportionately large to the functional action required of it, is conceded; but that every dilatation in the urethra is a pathological pouch, or every constrictions a stricture, or that, in order to restore one part to its normal condition, we must destroy the anatomical conformation of the whole of the urethra, I do not believe."

The existence of these dilatations and coarctations should be constantly borne in mind, and the normal conformation of the parts, so far as is consistent with the good of our patients, should here, as elsewhere in the body, be conserved.

Dr. Otis, to whom we owe more than to any other man for our knowledge of stricture and its results, avowedly disclaims the uniformity of the urethral caliber; nevertheless, his methods, and those of the profession who practice gradual dilatation with sounds, lead to the production of a uniform channel. Cutting alone never cured a stricture. It is the subsequent persistent, thorough dilatation that completes the work. This, if done with sounds, necessitates making the meatus as wide as the widest portion of the urethra. Loss of sexual power, urethral pockets, dribbling of urine, and curvature of the penis, as results of internal urethrotomy, increase in direct proportion to the thoroughness with which the operation is done. Experience convinces me that these results are much more frequent than the books would lead us to believe.

The cure of stricture by gradual dilatation is based upon the assumption that a retrograde metamorphosis is set up in the connective tissue, which causes its atrophy or absorption, and the coarctation is thus removed. If this is true, and if, after all, it is the dilatation that cures in internal urethrotomy, it seems to me that local dilatation at the strictured part ought to accomplish the same result without mutilation of the rest of the urethra. With this in view, I devised the urethral dilator described in the paper referred to above (New York Medical Journal, October 3, 1891, p. 371). The special points of interest in the instrument are its parallel separation over a limited space, its powerful mechanism, its applicability to all portions of the urethra, and its protecting rubber cap, which protects the mucous membrane from the edges of the metallic bars and prevents pinching when the bars are closed. After three years' further use of it I find no reason to alter the favorable opinion then expressed, and feel justified in recommending it to the profession in this supplementary report of cases treated by this method.

It would be puerile to claim that dilatation was the only
means of cure in the cases here presented. It has always been supplemented by the rational and accepted methods of treatment in these affections—such as hot water, boric acid, and permanganate of potassium irrigations, deep instillations of nitrate of silver, sulphate of zinc, etc., and the local application of remedial agents through the endoscopy and urethral speculum where necessary. The dilator simply takes the place of sounds and the urethrotome, accomplishing, I believe, better results with less pain in less time, and without any danger of immediate or remote unfortunate consequences. It is but just to say, however, that nearly all of these cases, as the tables will show, had been treated unsuccessfully by these same agents previous to the treatment by the dilator.

The following tables, taken entirely from private practice, embrace a variety of cases more or less similar, but all belonging to the class in which sounds and internal urethrotomy are generally used. The figures given all refer to the French system, and the measurements were made with the Otis improved urethrometer:

</table>
It will be observed that in two cases internal urethrotomy was performed. These were cases of hard, unyielding, cicatricial strictures. They were both in the pendulous urethra, and only the strictured area was incised, the subsequent dilatation being carried out entirely with the dilator. In one, curvature of the penis resulted; in the other the result was perfect. In six of the twenty-five cases internal urethrotomy had been previously done without success.

I believe these failures to be due, not to the operation, but to lack of persistent, thorough, subsequent dilatation. The pushing in and dragging out of sound after sound through a cut and sensitive meatus is so painful that only the most unsympathetic can resist the patient's entreaties to wait till another time, whereas with the dilator once in position the distention can be increased so gradually that the added pain is scarcely perceptible.

While the instrument may appear to some as a divisor, I disclaim for it any such intention, and I would warn all who may adopt it against the dangers of such a use of the dilator.

Very gradual dilatation has given me my best results. I seldom increase the distention more than two or three millimeters at a session, and these I make from three to ten days apart. In irritable patients, when the sitting must be far apart, the course of treatment is considerably prolonged. The use of the instrument is so simple I need not describe it. The caps should be taken off immediately after using and kept in a solution of bichloride of mercury (1 to 1,000). I keep one for each individual patient under treatment, to avoid the dangers of fresh inoculation.

The anterior urethra should be irrigated with a mild antiseptic solution before introducing the instrument, and where the urethra is sensitive, cocaine may be used with decided advantage. Care should be taken not to introduce the dilating portion through the neck of the bladder, for overdistention here is liable to cause incontinence of urine and traumatic cystitis.

The present series, together with those before reported, embraces sixty-five cases of which I have kept accurate notes. I have received letters from a number of physicians reporting with much enthusiasm the successful use of the instrument in a large number of cases, but have preferred to confine the tables to my own experience. The immediate results speak for themselves; but what is more conclusive to my own mind, so far as the ultimate value of the treatment is concerned, is the examination I have made of patients at a remote period from treatment. Of the thirty-five whose cases were reported in 1891, I have examined eighteen within the past six months. In only two was there any sign of a return of the stricture, and these, as my notes showed, had been under treatment only three and two weeks respectively. As the average time required for treatment is over six weeks, those two cases would hardly cast any discredit upon the method.

35 West Forty-Fifth Street.
ENTANGLEMENTS AND SHORTENING OF THE UMBILICAL CORD.*

By T. J. McGillicuddy, A. M., M. D.,
SURGEON TO THE NEW YORK MOTHER'S HOME MATERNITY HOSPITAL; CONSULTING PHYSICIAN TO THE ITALIAN HOSPITAL, ETC.

Probably in twenty-five per cent. of all labors the cord is either wound round the neck or is in some other anomalous condition. At the New York Mother's Home Maternity Hospital, in one thousand cases of labor abnormal conditions of the cord occurred at about every fourth or fifth delivery.

Suicidium fetus in utero is often referred to by the older writers as being of interest and of common occurrence; that it is not rare there can be little doubt.

Within a comparatively short time I have seen a number of specimens illustrating this complication of pregnancy. It is a pathological condition due to the movements of the fetus, by which the cord is twisted around the neck, body, or extremities so tightly as to shut off the blood supply, and thus cause its death. In the first specimen—

Case I, Figs. 1 and 2—which is at two months, the cord passes from the umbilicus around the neck once, then into the left axilla, then around the back of the neck, and around the other arm twice, under the axilla the second time, inclosing the forearm flexed upon the arm, then passing backward and downward to the placenta. It is twisted so tightly around the neck as to cause strangulation of the cord and consequent death of the fetus. It is much shrunched from having been kept some time in alcohol. For this specimen I am indebted to my friend Dr. M. C. O'Brien. In the next—

The mother was suffering from a deviation of the spinal column of such a character that the left hip occupied a higher plane than the right, probably resulting in the displacement of the uterus while it was expanding, and, consequently, irregularities in the movements of the fetus. As the labor progressed, presumably at full term, the child's heart-beats could not be made out. When the membranes ruptured, the characteristic bilious-looking discharge showed at once that there had been death of the fetus. Upon delivery, I found the child was of a deep purplish color and dead, with the cord twisted once, but with considerable tightness, around the neck. The cord was extremely small and thin. The only cause of death that could possibly be assigned in this case was strangulation by tightness of the cord about the child's neck, thus interfering with its circulation, shutting off the blood supply.

Case IV, Fig. 5.—When I saw this patient she had been twenty-four hours in labor. The membranes had been ruptured for some time. On examination, I found the child dead and the cervix thoroughly dilated. The head, which was
hydrocephalic, was above the superior strait. I applied my axis-traction compression forceps and delivered easily a decomposed fetus of apparently nine months' gestation. The cord very tightly enclosed the neck and passed around the shoulder and under the axilla. This was undoubtedly the cause of death.

Case V, Fig. 6.—In this case the cord was very short and it was wound twice around the neck. The shortening caused considerable haemorrhage three hours before delivery by traction on the placenta. The result of this was death of the fetus, which was of a livid color, but otherwise natural and healthy in appearance. The membranes ruptured only five minutes before the child was delivered.

Case VI, Fig. 7.—This was a case of acute puerperal inversion of the uterus, resulting probably from winding and shortening of the cord. Patient, a primipara, aged twenty-eight years, had albumin in the urine (ten per cent. by bulk). Labor lasted but six hours. Just at the final moment of delivery there was a severe pain, and the placenta, which was said to be firmly attached, was found along with the uterine inverted into the vagina. Hemorrhage was very profuse and the patient became exsanguinated. I believe no special attempts were made to replace the uterus, as the true condition of affairs was not recognized by those present. I saw her about fourteen hours after the accident occurred. The cord in this case was wound around the child's neck, wrist, and body. This case I reported in extenso in the New York Journal of Gynecology and Obstetrics for December, 1893.

In a case reported by Mauriceau the fetus was three months old; cord tightly stretched. Two folds of the cord encircled the child's neck, causing deep marks to be left there. There was separation near its origin at the navel.

My friends Dr. M. C. O'Brien and Dr. S. Marx report each a case of rupture of the cord due to shortening. Dr. O'Brien's patient was a young woman twenty-eight years of age. Examination per vaginam showed the fetus to be lying in an abdomino-anterior position, so that the hand, cord, and foot all presented at once. The uterine contractions were very strong; during the examination there was a sudden snap and a gush of blood, showing that the umbilical cord had ruptured. On delivery, which was performed by pelvis version, the right hand being gently pressed into the groin of the child, the stump of the cord was transfixed with a needle and tied. In this case a few moments' hesitation would have sacrificed the child's life.

In Dr. Marx's case the fetus was six months old, dead about one week; cord around the neck, and separated from the placenta at its attachment to it. At this point nothing was found but a shriveled stump filled with a coagulum of blood.

He has also given me the particulars of another case which occurred in his practice. In this one the fetus was about three months, and the cord was wound around the neck three times, and passed under the left arm. From the pressure of the cord the neck was very much thinned and drawn out.

Cuthbert, in the Trans. of the Edin. Obstet. Soc., 1875, reports the following case of strangulation in utero:

Mrs. P., aged thirty years, multipara. Miscarried for the second time on March 29, 1874. Her last menstruation was on
consequently, the foetus was about three months and a half old. No reason could be assigned by the patient for the accident. On examination of the foetus the cord was found coiled twice around the neck and, under the coiling, it was tightly tied in a single knot. The part of the funis from the umbilicus to the neck was completely on the stretch, and its whole length, from insertion in the placenta to the umbilicus, was about seventeen inches, or two times and a half the length of the foetus. The part continuous with the fetal circulation was round and of a natural size, but the other part—viz., from the neck of the foetus to the placenta—was small and cordlike.

There can be no doubt that the death of the foetus and, consequently, the miscarriage, was caused by the tying and coiling of the funis around the neck. Probably it was also hastened as the foetus grew larger by putting the smaller part of the cord on the stretch, which would tend to tighten the knot and coils. At the same time it would also stop the circulation.

As far back as 1823, Jameson, in the American Medical Recorder, reports a case, with illustration (Fig. 8), where the death of the foetus was the consequence of the funis having been tied around the body, the cord being of unusual length. The abdomen was almost cut in two by the constricting of the cord. It was one of twins, delivered at nearly full term, dead and somewhat macerated.

In cases of illegitimacy, the newborn child being frequently murdered by strangulation, this condition is of very considerable medico-legal importance.

In the London Medical Gazette, vol. xxxvii, Foster reports the following case:

He was called to a lady in labor with her first child. The labor was tedious and the child's head large. It was born dead, with the cord wound three times around the neck and under the right arm. After removing the cord, there was a discoloration of the whole neck, corresponding to the position occupied by the coils of the funis. The child appeared to be strangled.

Had the mother been unmarried, and the child secreted, it would have been looked upon as a case of murder. In children who have not respired these discolorations on the neck are generally the result of accidental pressure from constriction by the cord. It is not improbable that women have been unjustly condemned in these cases. There are instances on record where females have used the cord for the purpose of strangulation.

In my practice of obstetrics I have also often seen the influence a short or coiled cord has in obstructing labor. This condition, along with cases, has also been noticed by McSherry, Werder, Keiley, Campbell, Lusk, A. Lapthorn Smith, and others. In these cases there is delay without any apparent cause, and, when the forceps is applied, there may be either rupture of the cord or sudden detachment of it with placenta from the uterine wall, or an acute inversion.
of the uterus. To my mind there can be no doubt but this shortness or coiling of the cord is frequently the cause of accidental hemorrhage. In one case reported, the umbilical cord was torn away from its attachment at the navel and the intestines protruded through the opening. I have seen an infant with the cord wound four times around the neck. I make it a practice in every case to examine the neck for the cord and see if an immediate or hurried delivery is indicated. I run my finger down the back and side of the neck until it touches the shoulder, to ascertain if the cord is around the neck. Excessive coiling about the neck sometimes prevents flexion of the head upon the sternum, and this prevents the occiput from presenting. Besides the danger to the infant, this condition also causes danger to the mother by intensifying her sufferings and increasing the delay, and it also tends to exhaustion. The following cases, in this connection, show the delay resulting from shortness of the cord:

Mrs. D. T., aged twenty-six years, primipara. Labor normal with the exception of considerable delay after the child's head had reached the perineum; the pains were very powerful and neuralgic. The moment the head was delivered, it was noticed that the cord was wound tightly around the neck three times. At the moment of delivery the placenta followed immediately, drawn out by the shortened cord.

There can be no doubt that the coiling and shortening of the cord are also very frequently the cause of prolonged delay at the inferior strait. In connection the following case is interesting:

Mrs. N. J. S., twenty-eight years of age, pregnant with her second child. Her first labor was normal. During the first part of this present labor she assumed a kneeling position by the advice of her nurse. She called the attention of her husband several times to the fact that whenever she stretched her arms upward, even slightly, it produced a dragging sensation in the umbilical region, and this led her to believe that the cord was wound around the child's neck. The labor lasted nine hours, and during the second stage her sufferings were intense, and chloroform was required as the head presented at the vulva. I examined carefully to see if the umbilical cord was wound around the child's neck, and sure enough it not only tightly encircled the neck, but passed under the axilla and across the back. I hastened delivery by the forceps. The child was deeply cyanosed, and the cord was very thin and pulseless. A resort to artificial respiration in this case soon caused the child to breathe freely.

The mother's apprehension of trouble here seems to be founded on a fairly plausible theory, viz., that when the mother performs certain movements, the child performs the same movements, through either imitation or instinct. At any rate it is a firmly rooted belief among many of the knowing old women that pregnant women should not reach upward lest they cause entanglement of the cord. This theory may strike the reader as rather fanciful, but be this as it may, it should not be forgotten that most popular notions, no matter how fantastic, are often founded on a certain amount of fact.

A. F. A. King treats this condition by changing the woman's posture to a sitting, kneeling, or squatting one.

By this means he believes the power to labor is increased and the delivery often rapidly terminated, and that it is a better and safer method than by the forceps. Among the advantages alleged for posture are that the weight of the child assists by gravitation, the woman has much greater power in bearing down, and the uterus and its contents are forced more deeply into the pelvis. There is no question but that the abdominal pressure is increased by a sitting or squatting posture, as is well shown in the act of defection; that this was well known by the older writers is shown by the great variety of stools and chairs they used for obstetric cases. The Japanese, West Africans, American Indians, and others, assume the sitting or squatting posture, which is probably the most natural in delivery. The postural treatment has undoubtedly a tendency to somewhat relieve the shortened cord in these cases. For myself, I think that the abdominal contents and the uterus can be more easily emptied in a sitting or, much better, a squatting posture than in the recumbent position. This can easily be seen if we consider the anatomical conditions present and the direction and traction of the muscles involved.

THE NUTRITION OF INFANTS

FED UPON RAW, BOILED, PASTEURIZED, AND STERILIZED MILK.

BY HENRY KOPLIK, M. D.,

ATTENDING PHYSICIAN TO THE GOOD SAMARITAN DISPENSARY;
ASSISTANT ATTENDING MT. SINAI HOSPITAL (CHILDREN'S WARD), NEW YORK.

Soon after the presentation of the sterilization of milk for infant use the conversion to its general adoption was, one might say, general. It was seen that not only was the Soxhlet procedure well borne by the infant, but certain serious gastro-intestinal disorders common to infancy in the summer months were more easily controlled by its use, and some went so far as to assert that the mortality of infant life was reduced during the hot term. It will be seen that such an enthusiastic and general adoption of the sterilization of milk would not have been possible were there no grounds for such a course, at least partially so. Those of us whose experience antedates the introduction of the Soxhlet procedure would be first to realize the loss to infancy were we to-day deprived of its use. Under the above conditions, it was to be expected that opposition should finally come forward after the first wave of enthusiasm had subsided, and this was so, for in 1894 Leeds and Davis, working in Philadelphia, contended, apparently upon scientific and clinical data, that not only was the sterilization of milk for infant use detrimental, but the infants so fed actually suffered a slow process of starvation. That class of physicians who tenaciously held to the old, because, perhaps, it was too difficult or inconvenient to follow the new, shook their heads wisely, and the sterilization of milk for infant feeding and its accompanying modifications were labeled as a fad and its adoption sadly hampered for a time. The work of Leeds and Davis had certain deficiencies which were glaring to those whose experience compelled them to work in similar lines. While
repeating the experiments of Munk, who proved that the casein of the milk was digested artificially with greater difficulty as the milk was heated above 70° Celsius, they failed to show how this directly interfered with the real stomach and intestinal digestion of the same casein in the infant. The proposition to sterilize the milk at 70°, or below, by Leeds and Davis, was founded upon work tending to show that actual sterilization at this point is possible. This Pasteur and Hueppe and many others have proved beyond a doubt to be impossible. In fact, even 100° Celsius does not completely sterilize milk, as the author and Flügge have shown, following the footsteps of Hueppe. Again, in the clinical data brought forward by Davis to support the scientific dicta of Leeds, many of us involuntarily gained the impression that much of the material and its pathological and clinical aspects could be duplicated by sets of similar cases seen before the introduction of sterilized milk. In fact, the cases of marasmus brought forward by Davis as a proof of starvation from the use of sterilized milk were seen, and still are to be seen, in places and institutions where the sterilization of milk à la Soxhlet is unknown. In other words, the cause of starvation in these infants must be a deeper seated one than that seized upon by the distinguished American writers to prove their position.

One of the most noted objectors to the position taken by Davis in the article above mentioned was Escherich. This author asked for more definite data, especially as his experience, which was certainly as extensive as that of Davis, differed widely from the conclusions drawn in the American brochure. Heubner, while still working in Leipzig, showed that there was an actual increase in the weight of infants placed exclusively upon sterilized milk. Not that this fact was not widely recognized, but it seemed necessary to stem the tide of distrust awakened against one of the greatest advances in the management of artificially fed infants. Heubner, in a recent article, does not deny, nor does any other pediatrician, that there is a certain proportion of cases coming under the heading of infantile atrophy, or the term marasmus, which the sterilized milk and its modifications does not reach. These cases are mostly those of children in institutions, who have spent much time within the walls of the same. This author shows from actual statistics, however, that a very large percentage of cases of chronic intestinal disorders of a variety incurable before the introduction of sterilized milk are improved and cured by the same. It is foreign to the main theme of this paper to enter into all the details, pedantic and scientific, which certain earnest workers have brought forward since the time of Soxhlet's first paper in modification of the procedure of sterilizing milk.

I assume that most pediatricians will grant that the position of Heubner is correct: that a percentage, variable, of cases of chronic intestinal catarrh with atrophy are not benefited by sterilized milk. I shall, however, endeavor to show that this shortcoming in the sterilized milk is not at all a matter of heating to the degree of sterilization. It is not, as supposed formerly, a matter to be decided between the process of pasteurization or sterilization, as a certain German author has recently held, but is a matter, perhaps, inherent in the nature of the food itself, whether the food (milk) is ingested raw, boiled, pasteurized, sterilized, with or without the combination of breast milk. In approaching the subject I shall first show the inherent difference between the foods ingested by the breast-fed infant (mother's milk) and that of the artificially fed infant (cow's milk), and we shall also show in just what degree assimilation of these foods proceeds in the stomach and intestinal digestion of the infant. In the artificially fed infant we shall endeavor also to show how sterilization, or pasteurization, or boiling, may be practically excluded in the consideration of these important problems in connection with artificially fed infants, and how our attention must be directed in another channel to explain certain deficiencies in these infants.

The Casein of Cow's Milk and the Casein of Mother's Milk.—In the casein of mother's and cow's milk we have the bulk of the albuminoids which go to nutrition of the infant. The fats are for the present not under consideration. The earliest writers—Meigs, Dogiel, Soxhlet, Struve, Schmidt—thought that the only difference between human and cow's milk consisted in the amount of casein in the same. That the casein of both varieties of milk was chemically identical was thought to be an accepted fact. Soxhlet (1893), Dumas, and Calhouns made comparative analyses of the casein in the various animal species; but it was reserved for Hammarsten to first suggest that the difference between the two varieties of casein (human and animal) was a fundamental one, entirely apart from chemical composition. Wroblewski, in a most interesting contribution to this subject, made the discovery that the casein of woman's milk and that of cow's milk certainly showed differences in artificial digestion—experiments which seemed to confirm the suspicions of Hammarsten. He found that the strongest solutions of peptic were insufficient to dissolve the paranucleins deposited from cow's milk, whereas the nucleins of mother's milk never separated either with human or with animal peptic digestion. The experiments performed with peptic of the stomach of the child led to much the same results as the animal peptic experiments, except that the nucleins were separated in a finer and a more flocculent precipitate with the human peptic. The nucleins, an ever-increasingly important class of substances, proteids rich in phosphorus, were therefore separated from the casein in the digestion of casein obtained from cow's milk; whereas this was not recognized to be the case in mother's milk. It would lead us too far to go into the nature and importance of the nucleins; they can no longer be ignored, and their importance requires more exclusive study than can be devoted to them in this paper. Their presence in milk is a sign of some purpose, and the peculiar action of the paranucleins in the digestion of cow's milk should arrest our thought.

We will now try to consider briefly the studies upon the assimilation and excretion of nitrogen contained in the above forms of albuminoid bodies. Von Noorden showed that not only the stomach, but the intestine is the seat of digestion of the nitrogenous substances ingested into the economy. In
cases where the stomach digestion could be entirely excluded, he showed that milk was absorbed and assimilated in a most satisfactory manner. This seems to the writer important, for in the infant the amount of peptone proved to be present and formed in the infant's stomach has been repeatedly shown to be so infinitesimal, though undoubtedly present, that Epstein, Randhitz, and others assumed that as fast as the peptones are formed they pass into the gut. But in the infant the principal rôle in digestion is probably played by the gut, and this would be in conformity with experiments of von Noorden in the adult with milk diet—though milk is badly assimilated in the adult subject, at least not so well as in the infant. The stomach in the infant probably plays an introductory rôle in furnishing its ferments and causing preliminary preparation of caseins. Boas shows that the pancreas in the adult has a pep-tonizing action upon milk, though experiments in children in this direction have not yet been made.

Most authors, Voit, Pettenkofer, Rubner, von Noorden, Camerer, and many others, admit that the amount of nitrogen found in the urine, feces, and sensible perspiration is an index of the amount of nitrogen assimilated in a given fixed dietary. Von Noorden finds that a few days after the inauguration of a uniform diet the amount of nitrogen found in the feces is quite constant, whereas in the diet which is variable the nitrogen will vary widely. However, von Noorden finds that under a minimum allowance of diet he can reduce the nitrogen in the feces to almost nil. But when the minimal limit is passed, the nitrogen is supplied from the tissues themselves, and the nitrogen is increased in the feces above the quantity seen in the feces of those living on the minimum quantity of food necessary to existence. In plain words, the system lives on its storehouse of nitrogen, and starvation results. When an excess of food, as milk, is ingested, there is not an increase of nitrogen in the feces, but the nitrogen not needed is stored in the tissues and increase of weight results up to a certain limit.

Tschernoff was the first to establish the apparent paradox that in infants whose digestion, intestinal or stomach, is disturbed, or who are ill in a manner to react on the processes of the stomach and gut, the amount of nitrogen in the feces for a given weight of feces is less than in health; in health there is more nitrogen excreted through the feces. Lange explains this apparent paradox—for it implies a waste in health—by the fact that in illness the feces are much more dilute than in health, and that a given portion of the same would therefore contain less nitrogen. Lange shows the nitrogen excreted for the whole day in some cases thirty per cent, more than in health. Again, the feces in unhealthy infants contain more fat, and this in a manner accounts for the decrease of nitrogen in a given portion of feces. Lange made a number of extremely interesting observations in which he established that, though mother's milk was taken up and best digested as to its nitrogen by the gut, yet a sufficiently diluted quantity of cow's milk containing sugar of milk and well sterilized was also satisfactorily disposed of. Lange operated upon younger subjects—nurslings—than Bendix.

The work of Bendix is of especial interest in reference to the needs of older children who have been used to a mixed diet. His work, however, would not entirely be valid to draw conclusions as to the needs of nurslings. Bendix experimented upon children two to two years and a half old respectively. He put them upon a diet of white bread, chocolate, and for the most part milk sterilized and unsterilized. He comes to the general conclusion that in these older children the nutritive properties of the sterilized and unsterilized milk are about equal; but that disturbances of digestion diminish resorption, but not more so with the sterilized than with the unsterilized milk.

The question now naturally presents itself, how much nitrogen is necessary to maintain the nutrition of the economy, and especially of the infant?

Voit, quoted by Peschel, showed that the minimal quantity of albuminoids necessary to maintain a sound man in health was a hundred and eighty grammes per diem. Rubner, F. Hirschfeld, Kunagawa, and Klempere have shown that this figure is too high, and that albuminoids if rich in nitrogen are only needed to the extent of thirty to forty grammes daily. Though we can not draw conclusions from a minimal quantity of nitrogen, yet such experiments show that under the minimal regimen the body on the fifth day ceases to void nitrogen. An excess over the minimum is always necessary to the maintenance of health in the adult.

In the infant, Fehling found, experimenting upon the newborn, that in every hundred parts of the organism there was from 11.8 per cent. to 17.8 per cent. albuminoids containing nitrogen. Vierordt assumed that the mean for the first year of life was fourteen per cent. (Lange), which would give 2.24 per cent. nitrogen. Camerer found that fully twenty to sixty-five per cent. of the ingested nitrogen in the infant was taken up in the economy. This nitrogen does not all go to making up the increase of body weight of the infant. In atrophic children we find a marked nitrogen deficit, which, according to Camerer and Vierordt, is so great as not to be mistaken. What becomes of this nitrogen which is not taken to make body increase?

Vierordt thought that it could be relegated to the heading of "perspiratio insensibilis," but this is not in accord with the investigations of Pettenkofer and Voit, who showed that in man and in carnivora no such nitrogen is excreted by the skin in the form of gaseous exhalations. Again, von Noorden after this proved that excess of food does not necessarily mean increase of body weight. The increased functions of the gut demand ten per cent. or more of the caloric values under these conditions. Lange thinks that the above-referred-to nitrogen deficit can be explained by the great demands of the growing organism. The immense number of new-formed cells find no analogy in the adult subject. Von Noorden has found in convalescents from disease and in the rapidly growing organism the above-mentioned cell needs, if we might so call it, a striking feature. During growth the economy has a reserve of albumin or nitrogen. In other words, the newly formed cells of the growing organism take up nitrogen which does not finally appear as increase of body weight. Partly, also, we have
nitrogen used up in the metabolic processes of the gut (Camerer, von Noorden), and probably in the myotic processes of the same (Biedert).

In the above we have endeavored to show that in the nitrogen taken up in the system we have a clear and definite index as to the assimilation of albuminoids ingested into the economy. We can draw certain conclusions from a balance sheet drawn up to show in a given diet the amount of nitrogen excreted and the amount ingested, the amount which has been wasted in proportion to that ingested.

**Original Investigations.—** In my own work I have endeavored to determine from the amount of defect or loss of nitrogen the relative nutrition of children brought up upon a milk diet, boiled, pasteurized, sterilized, or combined with the breast. The infants were all nurslings, and the line of work consisted in placing them first upon a variety of milk, as in Cases III and IV, and then in the same infant after a week cease, mark off the movements thoroughly with some such substance as cragberry jelly, and then place the same infant, hitherto upon pasteurized or boiled, upon sterilized milk and in one case upon raw milk. The assimilation of the various kinds of milk could be thus accurately observed in the same infant and, we think, justly compared.

My methods of analyses were directed only to the faces, as these cases were ambulatory, and I did not know of any method of collecting the urine so that the eventual result could be relied upon. The Epstein method of collecting urine can only be applied in children lying quietly in their cribs. But as all my investigations included a careful analysis of the faces and their computations, certainly this gives us a useful index of the principal source of nitrogen loss to the system. Only cases in which I could be morally certain of methods and results were experimented upon. The food for the day was always accurately computed, the faces carefully collected from the diaper, and each day's faces were thoroughly dried in an oven at 95° to 100° Celsius for ten days at least to constant weight; the nitrogen in the faces of each day separately calculated. Bendix and others have thrown the faces together, dried a week's faces, and made two or more computations of nitrogen. As will be seen from a study of our tables, such methods do not show the nitrogen variations from day to day, and with such methods the absolute quantity of nitrogen excreted in the faces for the week can not be computed; only average figures are thus obtained by Bendix. In the method pursued by the writer no fewer than fifty nitrogen determinations were carefully made: each day’s faces were determined separately, and thus the absolute quantity of nitrogen in the faces for a week could be computed and no averages were made use of.

The Kjeldahl method was used to determine the nitrogen.

**Cases.**

**Case 1.—** Oscar S., perfectly healthy infant, aged three months, fed upon the breast and sterilized milk. Weight, eleven pounds and fourteen ounces; mother healthy, child not suffering from any present dyspeptic disturbances. The sterilized milk obtained from a well-known establishment, sterilized in quarts, and the requisite quantity for the babe poured off and mixed with water. Inasmuch as it is impossible to compute in this case the quantity of breast milk taken, the case is instructive to show only the percentage of nitrogen voided in the faces.

This is the only case in which we might average the percentage of nitrogen voided in the faces; it would give a percentage of 3.2 per cent. computed upon five days.

**Case II.—** Alice K., aged three months, one week, and four days; weight, eleven pounds; in good health; takes the same sterilized milk as Case I, but without the breast. Child suffers from no dyspeptic disturbances. Six days' feedings were computed in this case. A study of the table shows that in this time the infant ingested 2,680 grammes of milk. This bulk when dried would weigh 339.9 grammes, and would contain 14-6132 of nitrogen. We found that 0.04888 gramme was lost in the faces, a net result of 5.8 per cent. loss.

**Note.—** Several samples of milk were dried and an average of the milk supplied showed the dried milk to be 11.8 per cent. of weight of the whole milk.

Balance sheet of Alice K.: 2,880 c. c. milk ingested, 339 grammes dry milk ingested = 14-6132 nitrogen ingested, 0.04888 nitrogen lost in faces = 5-8 per cent. lost in faces of total taken into system.

Analyses of this dried milk showed 4-3 per cent. nitrogen.

It was not possible in either of the Cases I or II to change the diet of the infants as in the succeeding cases. The children were private patients, and the mother and foster-mother appreciated too keenly the responsibility of their charges to encourage us to suggest a cautious change, as had been successfully tried in the two following infants. The figures obtained, however, are useful in giving us data as to nitrogen deficit, which agree fully with what follows in Cases III and IV.

The figures show also how different the computations of nurslings must be from older children. In Bendix's work the older children voided fully twice the quantity of nitrogen in the faces, and these figures in older children above the age of one year resemble very much those seen.
in the adult, as can be confirmed by study of the work of von Noorden in the adult subject. The percentage of nitrogen excreted in the faeces varies daily much the same in the child fed upon the breast and sterilized milk as in the child fed upon sterilized milk. The nutrition in both infants was and is still, with the same foods, excellent, the increase in weight all that can be asked.

In the two following cases we have two infants who were successfully studied under a diet of pasteurized, sterilized, boiled, and raw milk. The results thus obtained must appear to all to be of value as indicating the degree of assimilation and digestion of the various foods in the same infant.

Case III.—Frank M., aged twelve weeks.

Family History.—Parents well; one stillborn child a year ago; a twin to Frank died a few minutes after birth.

Personal.—Child was well when born; would not take the breast; mother had plenty of milk; baby was emaciated when born; mother put it on cow's milk and water, equal parts. Child always had trouble with his bowels, always constipated, and for two or three days would have no movement unless castor oil was given; then the movement would be gray and hard.

Status.—Child somewhat atrophic; fontanelle 3/4 x 2/4 centimetres; skin of face wrinkled; has an old expression; sucking pads prominent; mucous membrane of mouth pale; tongue coated; throat normal. Chest bones very prominent; lungs negative; heart, apex beat within the nipple line; abdomen, veins prominent, note tympanitic; liver and spleen normal; extremities, folds in gluteal region, and upper thigh give evidence of emaciation; sleeps poorly; bowels constipated; respiration, 24; pulse, 104; temperature, 90°.

It must be distinctly noted that the subject in Case III, though not a normal infant, was not suffering active disturbances of digestion at the time of experiment. His condition was vastly improved as compared to the condition of the infant before it fell into our hands. The increase in weight proves the success of our care. Yet I should not call this infant healthy, for it was atrophic, and on this account think the data obtained are extremely valuable as showing that the amount of nitrogen excreted in the faeces and loss is not more than in the healthy infant, which we consider Case IV to be.

In my introductory remarks I showed that in infants whose condition entitled them to the term atrophic there was a disappearance of nitrogen in the system not accounted for by the increase of weight. In other words, cell metabolism goes on just the same as in the healthy infant. If a comparison is made in this infant between the total amount of nitrogen excreted in the faeces in the week under pasteurized milk, we find it to be much the same in total as in the week upon sterilized milk—0.511442 gramme with pasteurized milk, as against 0.68835 with the sterilized milk. The same infant lost of its total amount of nitrogen ingested 4.6 per cent. in the faeces under pasteurized milk, as against 4.9 per cent. in the faeces under sterilized milk. We can scarcely say that the 0.3 per cent. in favor of the pasteurized milk entitles us to draw any conclusions in favor of the pasteurized form of food.

Balance sheet: Total milk, 1,496 c.c.; total dry milk, 382.08 c.c.; this contains 12.744888 nitrogen; 0.68835 nitrogen lost in faeces = 4.9 per cent.

The same infant was placed upon the use of raw milk, and it was not possible to keep up this regimen longer than four days, for we found that even with great care a warm day in midwinter would sour the milk. But we did find, as will be seen by consulting the tables, that for three days the percentages of nitrogen in the faeces ran much the same as they did upon the pasteurized and sterilized milk. The total loss to the system in the faeces for three days was 3/4 per cent. of the total nitrogen ingested. These figures, of course, take no account of the loss through the urine.

There is one point, however, in this case which is of great interest, and that is the small amount of total faeces voided. By comparing with Case IV, which I consider a case as free from objection scientifically as we could select, it appears the residue as to faeces is small. Yet the infant obtained sufficient food, as shown by the increase in weight, its increased and rapid improvement under our care, and the nitrogen excreted in the faeces; for, had the food been insufficient, not only would the...
infant not have increased in weight, but the nitrogen in the faeces would have been reduced to a minimum, as established in the adult under a minimum milk diet by von Noorden. It may seem at first glance that the 0.3 per cent, in favor of pasteurized milk less nitrogen excreted in the faeces might be a nail on which to hang an argument in favor of the pasteurized milk. Especially is this striking when we find that during the three days of raw milk the nitrogen excreted in the faeces and its total percentage to the total nitrogen ingested was 1.5 per cent. less than with the sterilized milk; but this is a hasty conclusion. A study of my tables shows that in the absence of any dyspeptic symptoms the amount of nitrogen excreted daily varies widely—from 1.7 per cent. to 3.2 per cent.—under all diets. The nitrogen if low one day in the faeces is apt to be higher next day. This shows a variety of compensatory work carried on in the gut which our present methods do not reach. We must judge also by the increase in weight of the infant as well as by the nitrogen excreted. There is a point in these infants in which the smaller loss is compensated by a gain in the nitrogen excreted, resulting in a net balancing of all the nitrogen excreted to the same figure. I think that in the case of the raw milk a week or more would show possibly a figure much like that seen with the other forms of milk. In view of the wide excursions—from 1 to 0.5 of one per cent. or 1.5 per cent. difference—in the amount of nitrogen excreted, I think all careful observers will agree that from such figures alone we are not justified in concluding that the raw milk was more favorable to nutrition than the pasteurized, or the pasteurized than the sterilized. The infant all through the experiment, in spite of the variations and changes, actually increased in weight and improved, though in a miserable state before it fell into our hands. I may say in conclusion that this infant has been kept upon a form of sterilized food ever since the cessation of the above work, and after a month shows remarkable improvement, gradually leaving its signs of atrophy behind.

Case IV.—We now approach the fourth case. This child, before it fell into my hands, had been badly fed upon cow’s milk and patent foods. I started it upon a milk diet, and when it had advanced to a condition which I could call normal, being free from dyspeptic symptoms and increasing in weight, I began a study of its nutrition. I studied the assimilation of two main forms of food milk which had been simply brought to a boil and then taken off the fire, diluted, and given to the infant, and milk carefully sterilized at 100° Celsium by the writer’s assistant, Dr. Lewi.

Case IV.—Fred S., aged Five Months. Dietary. Milk brought to a Boiling Point.

Total nitrogen for seven days: 1.14454487

Balance sheet: 5,580 c. c. milk taken in: 688.2 dry milk taken in. This dry milk contains 30.969 nitrogen; 1.14454487 nitrogen lost in faeces in seven days = 0.3 per cent. loss nitrogen in seven days.

A study of the total nitrogen excreted by this infant will only confirm the justice of the author’s conservative views on the previous cases. It will be found, in the first place, that the amounts of nitrogen excreted in the faeces in both forms of diet differ widely in this case as in the previous ones, from 2.5 per cent. to 4.3 per cent. under both forms of diet. Moreover, the total loss to the system of nitrogen voided in the faeces was less under a strictly sterilized milk diet (4.3 per cent.) than under a diet of milk, which approached the pasteurized milk (4.5 per cent.), being 0.2 per cent. in favor of the sterilized milk. The contention of the writer in Case III not to conclude from the favorable 0.5 per cent. in favor of the pasteurized milk is therefore seen to be not without ground, for in this case the tables seem at first glance to be turned in favor of the sterilized milk (0.2 per cent.) ; but the truth is in the fact of the varying quantities of nitrogen excreted in the faeces, varying under certain laws we have yet to explain.

It may be mentioned as a corollary to the foregoing that this infant from the moment it was under observation to the present day has continued to improve on both forms of diet, boiled milk and sterilized milk. Under the sterilized milk there has been a steady increase in weight and general normal growth. We must note here the large amount of faeces, dried and moist, as compared with that of the atrophic infant in Case III, showing that the atrophic infant with fully the same amount of total nitrogen in the faeces (4.3 per cent. to 4.9 per cent.) had much less faeces, but at the same time the increase in weight was almost as great in one case as in the other.

Case IV.—Fred S., aged five months. Father and mother healthy. Child brought up on cow’s milk and water. At the age of three months and a half had a sharp attack of diarrhea which lasted two weeks. A month after this infant had another attack of indigestion, and this time there were convulsions, evidently connected with the inefficient attempts at feeding and subsequent intestinal myotic disturbances. When brought to the dispensary the infant had seven to eight movements daily; its diet was very dilute milk and oatmeal water. It had convulsive twitchings and convulsions, which were diagnosed as due to toxic intestinal absorption. The diet was regulated, and under treatment the infant improved and thrived, and when in
an apparently normal condition studies on its nutrition were begun. Initial weight, eleven pounds and three quarters. At the end of fourteen days’ observation, as noted in this paper, the infant had increased just a pound in weight.

We have thus placed infants upon raw, boiled, pasteurized, sterilized milk, and the breast, and also the breast combined with sterilized milk. In all cases a study of the writer’s results will show that the amount of nitrogen excreted compatible with a condition of perfect health and increase of weight varied widely—from 1.7 per cent. to 4.3 per cent.; and that the total nitrogen of one observed week varied—in one case favoring sterilized, in another the pasteurized, milk by a small fraction of one per cent. The amount of nitrogen excreted with the feces and the total loss of nitrogen to the economy is an index of the assimilation of the albuminous portion of the diet; but it does not tell the whole story, for in spite of wide variations we see not only the atrophic, but the apparently healthy infant increase in weight and thrive. We must consider to a large extent the metabolism, the amount of work also in the cells and gut of each individual infant, and far above all these there is the truth hidden in the character of the foods ingested. It would be manifestly unjust to conclude, as some authors, that, because the nitrogen excreted in the breast-fed infant is much the same as that of the infant fed upon artificial food in the form of pasteurized or sterilized milk, the latter forms of food are fully equal to the breast. This, it seems to the writer, is a one-sided argument. Again, no comparisons can be drawn as to the nutrition of infants fed upon raw, boiled, pasteurized, and sterilized milk from the nitrogen excreted in the feces, for an impartial study of cases experimented upon must lead to the conclusion that the main point at issue has been lost sight of in all these former experiments. Given a cow’s milk to start with, the nitrogen excreted seems to be much the same whether we pasteurize, boil, or sterilize the milk. The casein of the milk is assimilated much the same in infants upon pasteurized, sterilized, or boiled milk, but assimilated fully as casein of cow’s milk. The casein of mother’s milk, as proved by the experiments of Wroblewski, is an entirely different body from the casein of cow’s milk. Its casein has a nuclein and paranucleins which are readily assimilable; whereas in the cow’s milk the nucleins are partly insoluble and indigestible. Thus we see clearly how another important element has crept into the problems of infant feeding independent of any mechanical manipulations to which the food of the infant has been subjected. This may explain many things not ready of solution by the mechanical methods of chemical analysis. The delicate albuminoids and animal bodies rich in phosphorus (nucleins and paranucleins) present in mother’s milk can not be compared with those of cow’s milk. Nor can we lay the failures of artificial feeding of the infant entirely to the door of the mode of preparing the food, as has been attempted by the American and German writers. Accept, first, the fact that we are dealing with cow’s milk, and secondly, that we must give this food in a way to be free from objection (sterilization), but do not fasten on the mode of preparation an opprobrium which belongs at the start to the inherent nature of the artificial food itself. Future study must be directed upon the food and not the mode of its preservation. The preservation of the food and the limits of sterilization of milk, we think, are fixed and will not change until something better is suggested.

The authors who have presented the nitrogen excreted in the feces as a mark of the digestibility of pasteurized and sterilized milks have lost sight of the fact that the nitrogen excreted in the feces is indeed an index of the processes elaborated in the gut and the digestion of the milk, but only of the digestion of the casein, and this of the peculiar casein of cow’s milk. Such methods lose sight of the all-important points hinted at above, points which play an important rôle in the nutrition of the infant.

This work was elaborated in the Carnegie Laboratory, and the author wishes to acknowledge his obligations to Dr. John A. Mandel, under whose direction the analyses were conducted.

THE NEW ATMOSPHERIC GAS.*

By LOUIS FAUGÈRES BISHOP, A. M., M. D.

Occasionally a discovery in the allied sciences is so important and affects so directly the raw material upon which medical science is built up that, as physicians, we are entitled to participate in the satisfaction of the achievement. The following account of the discovery of a previously unknown though very abundant component of the atmosphere is taken chiefly from the accounts in the London *Nature*. The scene in the theater of the University of London just six weeks ago was in many respects unique as it certainly will be historical.

The Royal Society had invited two other scientific bodies

* Read before the Society of the Alumni of St. Luke’s Hospital, March 13, 1895.
to attend a meeting. The rush for tickets was such as might accompany the appearance of a great singer. It was known that Lord Rayleigh had succeeded in one of the most difficult of physical measurements, and had determined beyond the range of doubt the existence of a new and important element in the atmosphere. The existence of this gas had long been suspected. It was first suggested long ago by that curious and interesting figure in scientific history, Lord Cavendish, who in 1766 discovered hydrogen. One always thinks of Cavendish in his great house, filled to the roof with chemical apparatus, with the servants trained to understand by signs, lest in speaking they should disturb the train of his thoughts, and never to dust or disturb anything lest some experiment might be interfered with; the master of the house, a shy, reserved man, who devoted his fortune and his life to scientific discoveries. This remarkable man over a century ago suggested the presence in the atmosphere of a gas which has only been definitely described within six weeks.

Cavendish's reason for believing that this gas existed was of the same nature as that which led Lord Rayleigh to undertake the investigation which has occupied him for some years. It was noticed that nitrogen, as obtained from chemical compounds, was about a half per cent. lighter than when extracted from the atmosphere. Some years ago this fact was much discussed in scientific circles. The natural inference was that the nitrogen of the air was diluted by some other gas. Lord Rayleigh and Professor Ramsay finally succeeded by a chemical method in extracting a heavier constituent from atmospheric nitrogen. This gas does not correspond to any previously known substance. It has been given the name of argon. It is very soluble in water, and it is therefore found that it exists in large quantities dissolved in rain water. Nearly every argument of chemical philosophy points to the fact that it is an elementary body. When announced six weeks ago its atomic weight was believed to be forty. But the world-wide discussion which has since taken place brings out the conclusion of a large number of chemists, from the facts produced, that it is probably twenty.

Argon is prepared from the air by comparatively a simple method. The air is freed from water and carbonic acid gas by familiar methods; then the oxygen of the air is removed by red-hot copper, and there is left a mixture of nitrogen and argon. The nitrogen is now absorbed by red-hot magnesium, and we have argon remaining. The proportion of argon in the atmosphere varies from one twentieth to one hundred-and-twentieth, being about one hundred times more abundant than carbonic-acid gas. As yet no one has discovered any combination into which this curious substance enters, but its abundant existence in the atmosphere and necessarily in our bodies opens a wide field for speculation. How much is said and written about atmospheric conditions, about climate and its effects upon health and disease, and how little is really known! The great solubility of this gas, exceeding that of oxygen, means that in respiration it readily enters into the circulation. We have always known that there was a gas dissolved in the fluids of the body, believed to be nitrogen; we may reasonably expect that further analysis will show that argon is present in the fluids of the body to at least an equal amount with nitrogen. It is also possible that argon may form part of the number of organic compounds which have been supposed to be nitrogenous. Another interesting speculation is this: the property which has given nitrogen its enormous power in the production of explosives—that is, the tendency to escape from combination and assume the state of a gas—is still more marked in argon. Nitroglycerin is strong, but when we have "argoglycerin" what may we expect?

36 West Thirty-Fifth Street.

Clinical Report on Nuclein.

By CHARLES P. KNAPP, M.S., M.D., WYOMING, PA.

Amygdalitis.—G. G., aged fifteen years, female—family have "uric-acid diathesis"—schoolgirl; resides in malarial district; previous attacks of follicular amygdalitis lasting from five to ten days. Taken violently sick, October 29, 1894, at 4 p.m., after feeling badly the previous day. Saw her about 5 p.m. She was in bed, moaning from a severe headache and pain throughout the whole voluntary muscular system. She is a fairly well-grown and nourished girl, with the hollow eyes and sallow complexion of those who have an "insufficient liver." Skin flushed, dry, and hot. Temperature, 103°F.; pulse, 129; respiration, 24. Breath had a fetid odor. Tongue coated with a brownish fur. Tonsils swollen, so as to touch the uvula, and coated with a slight mucous discharge, which was easily brushed off, presenting a red and inflamed surface showing numerous small, pin-point, craters, with a slight white exudate in them.

A teaspoonful of Seidlitz salt was given in half a glass of water, and in an hour after a tablet of nuclein solution (Leedon-Aulde formula), to be repeated every hour for six hours, and then every two hours. At 11 a.m. next day, pulse, temperature, and respiration normal; patient free from all pain; bowels had moved about midnight, and she had slept fairly well after 3 a.m. Tonsils were reduced in size about one third, were not so red or painful, and the white pinhead points of the follicles, filled with secretion, were distinctly visible over their surface. Tablets were continued every three hours, and the patient was well the next day.

B. G., aged thirteen years, sister of the first patient. November 11, 1894, 10 a.m., case identical with above, save vomiting during first few hours. Treatment the same. Patient was able to return to school seventy hours after attack, well.

K. K., aged nine years, male. Does not differ in personal history, family, or symptoms from above. December 26, 1894, 2 p.m., one fifth of a grain of calomel every hour till the bowels moved. Nuclein tablet every two hours after bowels moved, which was four hours after 1 saw him. Well in seventy-two hours.

Malarial Disease.—M. Q., aged three years, female. Father is asthmatic; mother a plethoric woman, but never has had a milk supply for her children; had been brought up largely on condensed milk; has had catarrhal enteritis and asthma. Child anemic, poorly nourished, and stomach very irritable. Taken sick on January 9, 1895, with chill and fever. At 11 a.m. child tossing about in bed, slightly delirious. Temperature, 104°F.; pulse, 150; respiration, 30; vomiting, and frequent desire to go to stool. Urine scanty and high-colored, with disagreeable odor. Stools normal. The desire to go to stool evidently comes from irrita-
tion of the bladder, which I frequently find in children after a malarial chill. One fifth of a grain of calomel was given every half hour till bowels moved, which was in three hours—a large, loose, and greenish passage; then nuclein tablets, one every two hours. Next day, temperature, pulse, and respiratory normal, but patient very irritable, and refuses all food; half a teaspoonful of a solution of malted milk was given every three hours, and water freely as desired; nuclein continued same as before. Third day, slight chill and fever in the morning, but child able to be up in the afternoon; tablets continued as before. Fourth day, child able to be up; still cross and irritable and appetite poor. Malted milk and nuclein every three hours. No further return of fever or chills. The child continued to improve; other articles of diet that were suitable were gradually allowed, and nuclein given every three hours through the day till the end of the seventh day, when it was given three times a day for three weeks. The condition of this patient to-day is very satisfactory: from a fretful, puny, and poorly nourished child, she has gained in flesh, color, and digestive and assimilative power, to quote her mother, "upon candy medicine."

Mrs. M. D., aged thirty years, widow; good family history; a milliner by occupation. Has been sick with recurrent malaria for about three months, having an attack of chills and fever for two or three days every week or two, usually occurring about 11 A.M. or 4 P.M. of the day. Quinine and various preparations of iron had been taken during this time. Consulted me January 3, 1895, at my office, with general malaise following a two-days' attack of chill and fever. She is a well-nourished, slightly anemic, sprightly woman, who showed upon a careful examination no special features of disease. Put her upon a pill of quinine, iron, strychnine, and aloes. Reported on January 14th as no better, the chills and fever having occurred twice since her last visit. Tablet of nuclein given her, two an hour before meals and at bedtime. Returned on January 20th for more tablets, having had no attack since taking them, and at present writing continues well.

Scarlatina.—L. W., aged eleven years, female; schoolgirl. Family history excellent; has never been sick; slight constipation at times. Taken ill October 30, 1894, early in the morning, with vomiting, fever, and mild delirium. Scarlatina in the neighborhood. At 7 P.M. countenances indicated delirium and mental condition rather incoherent while lying upon her back in bed; there was nervous tremor; very easily startled. She is a well-developed, well-nourished, and healthy looking child. Skin dry, hot, and dusky red. Temperature, 103°; pulse, 180; respiration, 30. Breath has a chloroform-like odor; tongue red and coated with a thick white coating; throat a dusky red, with slight mucous covering, and tonsils swollen and having the glazed and dusky appearance of scarlatinat sore throat. Glands at angle of jaw swollen and tender.

Examination of other organs revealed nothing of importance.

Calomel, a fifth of a grain, was given every hour till bowels moved, preceded by a warm bath. Bowels moved in about five hours. Tablets of nuclein were then given, one every hour. October 31st, 10 A.M., patient had passed a restless night, but was feeling much better at time of visit. Vomiting had stopped. Temperature, 100° F.; pulse, 96; respiration, 22. Slight efflorescence on back of neck and chest. Throat still very red and sore; tongue and fauces also very red. November 1, 11 A.M.; Patient feeling quite well and bright. Temperature, pulse, and respiration normal. Redness of back of neck and chest still to be seen. Throat much better, but still sore; mucous membrane of fauces and tongue not so red. Her condition was so much improved, I doubted my original diagnosis. Stopped nuclein and put patient on elix. gent. c. tinct. ferri chlor.; told her mother to send for me if patient did not progress well, and to keep her in the house and at home for two weeks.

Called again on November 5th on account of swelling of the glands of the neck. Superficial glands all enlarged and tender, especially those at the angle of the jaw; patient quite anemic, with pain in joints, and without appetite. Urine dark-colored and scanty and containing a small quantity of albumin. These are the frequent sequel of scarlet fever.

I had stopped nuclein too soon; began giving a tablet every three hours, and Seidlitz salt to keep bowels soluble. In five days all these symptoms had disappeared. The patient was then put on syr. ferri iodid. (Squibb) in small doses and was soon well.

Tuberculous Adenitis (Cervical).—H. H., aged fourteen months, female. Family history of tuberculosis on both father's and mother's side. Had lost a child of five years with what I considered tuberculois of the kidney. Child had had bronchopneumonia when seven months old. Had not been well for about a week; was very anemic; glands about the neck were all enlarged, and the submaxillary glands were very large, red, and tender. She could not move her head, and was unable to nurse the breast. Saw her December 24th at 3 P.M.; was in bed and lying very quiet. Temperature, 100° F.; pulse, 120; respiration, 22. Tongue coated; bowels constipated; urine scanty and high-colored, but did not contain albumin: lungs and heart normal; spleen slightly enlarged; other organs normal.

Calomel, a fifth of a grain, was given every hour till bowels moved, which was at 10 P.M. A nuclein tablet was then given every two hours. December 25th, 10 A.M.; Condition not changed. Was called again at 7 P.M. Child had taken no nourishment during the day. Temperature was 108° F.; pulse, 150; respiration, 26. Phenacetine, half a grain, was given, and the same quantity at the expiration of an hour; then nuclein was given as before. December 26th: Child much better. Temperature, 100° F.; pulse, 120; respiration, 22. Neck still stiff and could not nurse the breast. Malted milk was given in solution, quantity of three ounces every three hours. December 27th: Pulse, temperature, and respiration normal; all glands were decreased in size, and by continuing nuclein every three hours the child was in fair condition, and the enlarged glands had disappeared by January 7, 1895.

Patient was then put on emuls. of mnrnhue. On January 14th mother called at my office for more tablets, saying the child was becoming peevish and fretful, and the glands were enlarging again. Saw her next day. Slight enlargement of glands, but no rise of temperature. Nuclein was given, a tablet every three hours, for remainder of the month. Child improved rapidly, and at present time is in better health than ever before. During the sickness she was weaned from the breast, and is now on a more generous but carefully regulated diet, the principal part of which is malted milk.

I am indebted to Dr. William H. Fauks, of Luzerne, Pa., for the following report:

Diphtheria.—Was called November 22, 1884, to see Miss M., who had contracted diphtheria while taking care of two diphtheria patients, both of whom died after a short illness. She was taken ill on the day previous, and when I saw her the tonsils were swollen, almost closing the throat, and the false membrane covering them extended at one point as far up as the soft palate. Having just received a sample bottle of nuclein solution, I determined to try it, and at once injected twenty drops, and repeated the dose three four times until four injections had been given, after which the same quantity was administered twice daily for the following three days. The general condi-
tion of the patient was much improved after the first twenty-four hours, the countenance wore a more cheerful aspect, and there was a condition of well-being that I had never seen before under similar circumstances. On the second day the membranes began to melt away, not peeling off or shriveling and leaving a raw surface under them, as we usually see, and on the fifth day there was scarcely any membrane to be seen, and the tonsils presented an almost natural appearance. There were no sequelae, save paralyses of the soft palate and a feeling of faintness on exertion. An examination, bacteriologically, of the exudate showed the Klebs-Löffler bacilli.

Since then I have treated two children, aged one and four years, with gratifying results. In the case of the one-year-old patient, it was the only one of a family of four that recovered, and the only one treated with nuclein in that family. Local applications and the usual remedies were given in these cases as well as nuclein.

**NUCLEIN AS A DEFENSIVE PROTEID.**

**ITS SUBCUTANEOUS ADMINISTRATION IN THE DIFFERENT GRADES OF DIPHTHERIA, ACCOMPANYED BY A CLINICAL REPORT OF FIFTY-THREE CASES.**

By J. MOUNT BLEYER, M. D., F. R. A. M. S. NAPLES, SURGEON TO THE NEW YORK THROAT AND NOSE HOSPITAL; AND TO THE NEW YORK WEST SIDE GERMAN CLINIC; MEMBER OF THE SOCIÉTÉ FRANÇAISE D'ÉLECTROTHERAPIE, PARIS; CORRESPONDING MEMBER OF THE MEXICAN ACADEMY OF MEDICINE; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, ETC.

In philosophy facts are useful only so far as they lead to a true theory; and a theory is only a method of showing the true relation which exists among the facts. When a theory is, or seems to be, well established, any facts which appear to militate against it are apt to be disputed or received with caution or incredulity. For this reason, mankind have been disposed to oppose new discoveries and innovations, which render a change necessary in their theories, creed-like opinions, and habits. It is not because they are unfriendly to improvements, but because they doubt the reality of the discovery or the real practical importance and utility of the proposed change. It rather demonstrates their love of truth, for they, like St. Paul, verily believe that they are doing their duty by resisting the introduction of error. But if the new truth can be made to harmonize with the old opinions, it is then cordially received into the family of admitted facts which go to constitute our favorite theories. The facts of a science may be compared to the scattered and broken bones of a skeleton, while a theory is the method by which they can be put together and proved to belong all of them to one animal. The facts in "cellular therapy," organo-therapy, or therapy of substitution, call to mind a collection of strange bones once found in England which apparently belonged to animals of a different kind from any that had ever been known to exist on earth. Some very learned and sagacious men at first denied the existence of the bones; but when they were dragged to light and produced before them, so that they could no longer avoid acknowledging their existence, they declared that such enormous limbs must have had a supernatural origin, and that they were undoubtedly the bones of fallen angels. Upon further examination by scientific men, it was found that they were bones of whales and other marine animals that had been ages ago "in the deep bosom of the ocean buried," and that the place had been afterward raised to eminence, like classic Delos, upon the shoulders of an ambitious and aspiring volcano. Only a few years have swept past us since a novel and peculiar tendency has made itself evident in medicine, more particularly in the application of certain remedies, which shows a tendency which can not fail to attract attention, and, from records which already fill the files, showing thereby the already achieved results, rouse our expectations. When I simply speak or make mention of the words myxoeclia and thyreoid treatment, it will at once give the hint; generally speaking, it is the tendency to look for the cause of certain disorders to the demolished or deficient function of a certain organ or system of organs, and, when this cause has been sought out, to try to re-establish the status quo by introducing into the body the parenchyma or expressed juice of the corresponding organ of a healthy organism, usually that of an animal. By this mode of application we get a substitution or compensation of organic material, rightly termed "therapy of substitution" or organo-therapy.

From the very babyhood of the science of medicine, even at this period of civilization in some countries, human and animal secretions and organs have been used for the treatment of disease, certainly in a very crude and primitive manner; but all the same, the notion, however dim, must have been present in the human mind. Through the workmanship of such savants as Malpighi, Leuenhoek, Bichat, and Schwann, histology brought to light all the facts that all tissues have their birth in cells; pathology, through Müller and great Virchow, "cellular pathology"; bacteriology, through Lamarck, Ehrenberg, Royer, Da-vaine, Pasteur, and Koch, and physiological and pathological chemistry through Horbackzéwski, Althouse, Lee, Vaughan, and Novy have all added to the proof that the entire science and art of medicine rest upon this pedestal—"The ultimate cell, its functions and enemies." If all that is true, then the advancement of therapeutics upon a rational basis must be linked inseparably with a more accurate knowledge of the life history of the cell.*

Dr. John Aulde, of Philadelphia, promulgates a most rational theory of cellular therapy. He speaks of it as a method in therapeutics of exhibiting properly selected medicaments with a view to the restoration of cell functions. It is in line with the conservative process of Nature treatment of diseased conditions. As cellular pathology is concerned in studying retrograde metamorphosis, so cellular therapy aims to apply scientifically those remedies which investigation and experience have shown to possess curative properties by restoring the cell to its normal function. This theory is not entirely a new one, as some of the older literature has pent up in it some of the views just expressed.

Speaking of the cell, we find it an ultimate living principle which is visible to the eye and understanding. It

---

BLEYER: NUCLEIN AS A DEFENSIVE PROTEID.

April 13, 1895.

Nuclein has functions of eating, sleeping, reproducing and defending itself, subject to the changes wrought by heredity and environment, and from the latest investigations we find in Professor Schaefer's remarks the following: "The protoplasm and nucleus form the living substance of the cell. There appears, however, to be yet another something which, although in point of size is of very insignificant dimensions, yet in point of function may perhaps be looked upon as transcending in importance, in some respects, both the protoplasm and nucleus, the attractive particle." Quoting further from Martin Heidenhein: "The attractive particle is morphologically, physiologically, and chemically a structure sui generis. It is almost as minute an object as it is possible to conceive. It imitates and directs those processes which result in the multiplication of the cell, and indirectly, therefore, it is concerned in directing the general growth of the individual and ultimately the propagation of the species." Therefore, says Dr. Knapp, we can assume from the contribution that the cell has a brain and nervous system. Professor Sanderson also, before the British Association for the Advancement of Science, sounds another chord with the above views by saying: "The process of lymphatic absorption, which before we regarded as dependent on purely mechanical causes, is in a great measure due to the specific energy of cells and not to the various processes of secretion; the principal part is not, as we were inclined not many years ago to believe, attributable to liquid diffusion but to the same energy." Dr. Knapp further takes from this standpoint the view that for the present purpose, however, it is sufficient to know that the cell is the seat of all the functions of the human body—nutritive, secretory, excretory, and correlative—and that in health and disease we are concerned with the cell and not with the organism as a whole; that the vital processes take place in the cell and that the equilibrium between anabolism and katabolism, repair and waste, may be taken as a definition of health; that certain physiological functions of the cells—chemotaxis, phagoctysis, cell proliferation, and defensive proteids—are the functions concerned; immunity, vital resistance, and the arrest and cure of disease. It is already a known fact that certain cells or certain groups of cells have certain powers of reaction and irritability, and it is reasonable to suppose this power belongs to all cells. Stimulus and changes in the vicinity and environment of the cells produce alterations and changes in the cell; therefore it is concluded that the cell may be modified by medicaments, and assume this to be the basis of the physiological action of drugs, seeking not their mechanical effects, nor effects upon the pulse, respiration, and temperature alone, but their action upon the cell, whether the action is demonstrable in the laboratory or inferred from the clinical result.

It does not fall to my lot in this paper to attempt to classify remedies according to their effects upon the cell and their power of restoring cell function. This classification has already been done by a most ably written communication read before the medical association by Dr. Knapp, of Luzerne County, Pennsylvania. The attention which I wish to draw is to one of those special medicaments that stimulate the defensive action of the cell. It is "nuclein." It is not only from this one which is embraced among the latest researches from which we shall reap the most practical result, but also from the many already listed, such as thyreoidin, antitoxin, séquardine, and toxins, with a host of others to follow, corresponding with each infectious disease and all characteristic lesions of each organ. This and other defensive proteids which we have to thank the physiological and pathological chemist for discovering (nuclein, proteids, and albuminoids), and from which such deductions have been made; that the power to resist or withstand disease rests in the defensive action of the cell, and that the rational treatment of disease of an infectious character is to stimulate this action, or to add the proteid, it is but plausible to say that from such therapeutics we are to secure immunity and cure in infectious diseases. With the aid of modern chemistry this onward march will continue and add newer substance from time to time analogous with the structure of well-known bodies. These substances will be submitted to the judgment of the medical world in the hope that they prove more useful than the preparations in present use.

Nuclein is not a new substance, and the study of nucleins dates back to the period of Braeinot (1831). Only in recent times has there been any systematic attempt made to determine their chemical and physiological properties with a view to their employment as remedies. Among the students of nucleins rank such men as Quevenne, Schlossberger, Miecher, Béchamp, Hoppe-Seyler, Lubavin von Jaksh, and Ploeze—these were the pioneers. Then came along in 1879 Kossell, who began to teach us the germicidal properties. Ten years elapsed before any attention was paid to these substances until again Altman revived their study. Lieberman prepared at this time an artificial nuclein from albumin and metaphosphoric acid. The men who are entitled to the latest honors in bringing about the most practical work in this line are Geohagan, Malpatti, Korbachewski, and finally in 1893 Vaughan, of Ann Arbor, Althouse, of England, Germain Sée, of France, and Audel, of Philadelphia.

Professor Vaughan has done much to introduce and experiment toward the preparation of a definite nuclein for therapeutic purposes. In a paper at the last Pan-American Congress, Professor Vaughan made the following statement regarding nucleins: "These substances—nucleins, proteids, and albuminoids—when introduced into the bodies of animals in certain amounts and under certain conditions have the property of stimulating the activity of certain organs in the animal, so that those organs produce and supply to the blood an antidote to the substances introduced; the glands that manufacture these immunizing agents are the spleen, thyreoid, and bone marrow, and the antitodal substance is a nuclein."

"Nuclein is a physiological remedy; it plays its daily role in the economy.* Wherever waste products are to be handled, there Nature supplies nuclein, and in that complex chemical and physiological workshop, the alimentary canal,

the antiseptic properties of nuclein constitute the balance wheel of the digestive process. Besides its action upon the blood it has stimulant action upon the brain and nervous system, which accounts for its influence upon the aged and in chronic maladies. A wide field of usefulness is therefore open. Whatever assails the cell, it is useful per se as a neutralizer of the enemy and as a stimulator of defense. Whatever lowers the tone of the system, so that the correlation of forces is impaired and the defense broken down, it is useful to repair the breach by direct chemical action, or as a stimulant to normal work through the regular physiological processes."

We can call nuclein a most prominent aspirant in the field which happily illustrates the doctrine of cellular therapy. Scientifically, nuclein is described as a phosphorized proteid, the phosphorus existing in the form of nucleinic acid combined with a rather complex basic substance. This basic substance yields, as decomposition products, one or more of the so-called xanthin bodies—adenin, guanin, sarkin, and xanthin. The available sources are as follows: Yeast cells, yolk of egg, the spleen, the blood, the testicles, the bone marrow, the brain substance, and the thyroid and thyrmus glands.

The Preparation of Nuclein and its Source.—Yeast nuclein (Professor Vaughan’s) is prepared by extracting brewer’s yeast with diluted alkali and subsequent precipitation with dilute hydrochloric acid. The precipitate is redisolved with alkali and reprecipitated with acid several times, and is finally dissolved in 0.25 per cent. of potassium hydrate. As before said, nuclein is also made from animal sources, and is obtained by means of artificial digestion, after a preliminary maceration with a mixture of equal volumes of absolute alcohol and ether. The product is then usually digested for some days with peepin and 0.2 per cent. hydrochloric acid, the undigested portion being collected upon a filter and worked, first with 0.2-per-cent. hydrochloric acid and then with alcohol. The final step consists in dissolving the precipitate in 0.5-per-cent. solution of potassium hydrate and filtering through a Chamberlain filter without pressure.

From all the foregoing glowing arguments presented to us by the above-cited gentlemen, all of eminence in either one branch of the science or the other, and whose veracity can not be doubted, either as regarding their word, power of observation, or ability, I concluded from some of my own experiences with nuclein to put this remedy to further clinical tests in the treatment of diphtheria and allied affections of the throat with different degrees of severity.

Of the fifty-two mixed cases herein reported, thirty-five were follicular amygdalitis, six pseudo-diphtheria, and nine true diphtheria. I take great pleasure in giving the results obtained by subcutaneous injections of this most important of defensive proteids, nuclein.*

I found that nuclein showed its specific effect upon all these varieties of diphtherias with a prompt action: the form known as angina lacunarisis sive follicularis, a disease in which the surface of the tonsils and fauces is inflamed and is stippled with curdy-white or ash-gray points or patches; in which there is an absence of anything like a deep slough; which usually disappears under appropriate treatment and which may simultaneously affect a number in one family and prove fatal sometimes. It has been said by authorities, however, that this is not a true diphtheria to begin with, but that the affected parts in this condition serve as a good cultivating ground for the diphtheria bacillus, and that in this condition the patient is particularly susceptible, and that the diphtheria is really a secondary and superadded disease. We are reminded by Hamilton: "Many instances of diphtheria, however, commence as angina lacunarisis." He further says that all forms with a marked condition are considered by him as of a diphtheritic nature. From the many suppositions by the most prominent bacteriologists, I find that the treatment herein advanced is indicated, both as a prophylactic and curative agent. Dr. A. L. Chamberlain, in discussing under the head of the physiological rôle of antitoxin inoculations, takes the following stand: "Having shown the utter fallacy of the claim that antitoxine inoculations are effective by reason of any chemical or physiological properties which they might possibly embody, it remains to give a rational explanation of their physiological rôle in the human economy. Recalling the fact that blood serum possesses antiseptic properties in its normal condition, and the additional fact that the blood serum of persons recovered from this disease is able to confer immunity on others who have been exposed, and further, that when the disease is in its iniquity inoculations with this peculiar toxalbumin will exert a favorable influence upon its course, we have some substantial data at hand as a basis for further investigation. All the evidence points to the probability that the introduction of this toxalbumin into the circulation has the effect of stimulating cellular activity, and that either by a gradual process or immediately the cells are educated to resist the destructive effects of the disease. It is a well-known fact now that the multinuclear white blood-corpuscles secrete or manufacture a powerful antiseptic substance called nuclein, which serves as a natural protection against diseases of every description. It is also admitted that through the presence of this substance in the blood, in the lymph, and in the various secretions, decomposition is prevented, particularly decomposition in the secretions of all mucous surfaces. Indeed, some have gone so far in this direction as to assert that the mucus secreted by nasal mucous membranes is itself an active antiseptic. It is not unreasonable to assume in this study that when a person is attacked with diphtheria these cells gradually acquire the ability to secrete a product which is inimical to the bacterial products taken into the circulation during the progress of the disease; hence the great value of blood serum obtained from one of this class. By the use of pure cultures from the disease we introduce into the circulation an irritant which has the effect of stimulating the functional activity of the white blood-corpuscles to produce something which shall counteract

* In this connection I should say that the nuclein employed in the following cases was manufactured by Parke, Davis & Co. after the formula and under the supervision of Professor Vaughan, with the exception of the four cases reported in the American Therapist.
the effect of the poison; this substance in solution coming in contact with the cells at the point of elimination augments the normal antisepctic properties of the secretions; moreover, it supplies an excellent illustration of the theory promulgated under the name of cellular therapy."

In diphtheria of this type fifteen to twenty minims of nuclein hypodermically administered twice in one day, dividing the injection twelve hours apart, gave a most remarkable result within twenty hours in every case. No other remedy was employed, excepting salt-water gargling or douching, simply to remove the loose débris lying about the mouth and throat. In but a small percentage of the cases the temperature mounts after the first injection from 0°1 to 3° F.; but the high-temperature rise was an exception. The pulse runs from 100 to 160. All symptoms usually found present in this form leave the patient within the first twenty-four hours. Some fever remains for thirty-five hours, then disappearing, minus the exhausted condition. Nuclein seems to possess with all its specific action another advantage—that of a dynamogenetic power, increasing the vigor of the central nervous system.

In that type known to us as pseudo-diphtheria the same promptness of action was immediately noticeable, with that one exception that a longer time (three to four days) was wanted for a complete recovery. In these patients the injections were made also in divided periods of time, but oftener exhibited (every eight hours), each consisting of twenty minims, and continued for three days. In addition, the gargling or irrigation of salt water every hour is practiced, the entire number of eight patients recovering within four days.* Nine true diphtheritic cases were treated upon this plan of medication, and seven of them recovered, one of them undergoing tubage for stenosis, a remarkable percentage. The cases of the first four of these patients were reported in full in the American Therapist, November, 1894, all of whom recovered. Since that three other patients have received injections, and all have died from toxæmia and heart paralysis. The first two patients were not injected until the third day of the disease, which ran a most rapid course.

That no mistake in diagnosis should be made in all these cases regarding the specific character of the disease and not confounding it with some similar form, the membranes taken from these patients were all subjected to a critical bacteriological test.

The seventh of the recovered cases is one which came under the treatment since the above-published report appeared. The patient was seen in consultation with Dr. L. Sandberg, of New York. The injection was not made until the fifth day of the disease, and on the sixth day stenosis was so marked that tubage had to be performed. The injections of ten minims were administered subcutaneously four times daily for the first day and thereafter three injections for seventy-eight hours. No extension of mem-

* Two of these patients were seen in consultation with Dr. Pfeiffer, one belonging to Dr. Hatch and the other to Dr. L. Sandberg. I am also indebted to Dr. Jacobson, visiting surgeon to Denili Quinquinary, children's department, for sending me ten cases for injection which were watched by himself.
THE SERUM TREATMENT OF DIPHTHERIA.

We all remember the decided impression made on us not long ago when Husemann, of Berlin, raised his voice against the view that the Klebs-Loeffler bacillus was pathognomonic of diphtheria and against the idea that the antitoxic-serum treatment was curative of true diphtheria. What he said came like a thunderbolt to disturb the serene progress of the treatment toward coming into vogue. He spoke with quasi authority, and men paused to reflect, to go over the ground again, to re-open the case, which had been looked upon as almost as good as closed. If this was the effect of Husemann’s criticism, made from a theorist’s point of view, what weight may we not look to see accorded to the radical protest made before the New York Academy of Medicine last week by Dr. Winters, resting on his own painstaking and protracted clinical observation in the Willard Parker Hospital and elsewhere? Nobody who knows the medical profession of New York can question Dr. Winters’s astuteness as a clinician, and we do not conceive it to be possible to bring up any circumstance or condition that may reasonably be held to have tended to warp his judgment in this matter. We shall not summarize his conclusions here; the substance of what he said, nearly in his own words, will be found in the report of the proceedings given in this issue of the Journal. Opinions will vary, of course, as to whether or not one holding Dr. Winters’s convictions may properly go so far as he went in condemning the methods of conducting the antitoxin treatment adopted in New York under the auspices of the local board of health. We do not interpret what he said in that direction as condemning either of the board of health as a body or of individuals acting under the board’s authority. On that score the case is simply this: Some men are firmly convinced of the great promise held out by the serum treatment, if not of its efficacy having been sufficiently demonstrated, and they are bound in conscience to act accordingly; others with quite as positive convictions to the contrary are equally under a conscientious obligation to protest. The warmer the discussion grows, the sooner are the questions involved likely to be answered to the satisfaction of the profession at large, provided side issues are not clothed with undue importance. Until Dr. Winters presented his observations it seemed to most of us that the antitoxin treatment was destined to meet speedily with general acceptance, coupled with the drawback that an occasional death attributable to it must be expected. Now, however, we appear to be far from such a conclusion. Much more experience, much more sifting of facts must yet be gone through with before the full truth will be known.

There is one point that seems worthy of more attention than it has thus far met with. It was mentioned by Dr. Winters, but is more fully treated of in Dr. Armstrong’s letter printed elsewhere in this issue. We mean the destructive effects of an animal’s serum when thrown into the circulation of another of a different species. Doubtless the conditions ordinarily attending the use of the horse’s serum therapeutically differ materially from those present in Hayem’s and others’ experiments alluded to by Dr. Armstrong, but it strikes us as reasonable to suppose that exceptionally they may be near enough alike to account for a death now and then as the result of this way of treating diphtheria.

MEDICAL AFFAIRS IN INDIA.

There appears to be deep discontent among our professional brethren in India. Whether it is confined to the non-official physicians of British birth domiciled in that country, or whether it extends to the native practitioners, we do not know, but there seems room for surprise that it affects all but those who are in the military service. Some of the Indian medical journals have lately printed editorials and communications bearing now on one aspect of the grievances complained of and now on another, but we have not yet noticed any connected statement of the whole state of the case. There is what is known as the “covenanted medical service,” and there is the body called the “uncovenanted medical service.” Precisely what the difference is between these two bodies we have not yet divined, but we presume that the one is more favored in government circles, more “official,” than the other.

If we may judge by an editorial article that appeared in the March number of the Medical Reporter, of Calcutta, the hope and expectation had been entertained that the Indian Medical Congress, which assembled in Calcutta in December, would furnish an opportunity for those Indian physicians who were not connected with the official medical service to show forth to the world something of what they had achieved under difficulties, as a consequence of which the government would perhaps be induced to enlarge their facilities. In this they were disappointed. The president of the congress, whom they seem to have looked to as their spokesman, is said to have put his foot into it, to have given a political turn to the congress, and to have played into the hands of the official class. It is hinted that in all this he had the powerful co-operation of Mr. Ernest Hart. Among other things, it is said that the heightened educational facilities that should have been asked for in behalf of the provincial schools were advocated chiefly if not solely for the benefit of the officers of the medical service, men who are only temporary residents of India, and that, too, not at the expense of the home government, but by laying a new tax on the people of India—a tax on salt—that they are declared to be utterly unable to pay. Why, indeed, they should pay it is difficult to understand, but we can make no pretense of knowing the facts and appreciating their bearing well enough to warrant us in
MINOR PARAGRAPHS.

DEGREES IN PHARMACY.

In the April number of the Pharmaceutische Rundschau, a German pharmaceutical journal published in New York, there is an English editorial article on pharmaceutical degrees. While the writer chivalrously and justly insists that pharmacy is something more than an art, and consequently that its practitioners are as a body entitled to be looked upon as a profession, yet he modestly maintains that the pharmaceutical curriculum is not sufficiently scholastic to attach to the degree of doctor of pharmacy a dignity that the medical schools would think commensurate with its lofty designation. In this we think he is correct.

OBJECTIONS TO THE ANTITOXINE TREATMENT OF DIPHTHERIA.

Fuer in states in the Berliner Klinik for March that the drawbacks to the use of antitoxine are its uselessness in secondary septic infections and in diphtheria of the bronchi, and the unfortunate after-effects, such as purpura, albuminuria, hemorrhagic nephritis, arthritis, and other phenomena of systemic intoxication that are sometimes manifested from the eighth to the fourteenth day after the injection.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending April 9, 1895:

The late Dr. Alfred L. Loomis.—At a stated meeting of the New York Academy of Medicine held on Thursday evening, April 4, 1895, the following resolutions were passed:

Whereas, Our associate and former president, Alfred L. Loomis, M. D., LL. D., has been removed from among us by death. Therefore be it

Resolved, That the death of this distinguished man in the profession of medicine has lost one of its ablest teachers, one of its wisest leaders, and that the Academy of Medicine has lost a fellow who contributed largely to its present prosperity; for, at a time when it had become important that a new seat should be secured, it was greatly through the courage and enterprise of Dr. Loomis that this was accomplished and the present large and sufficient building erected.

Resolved, That in view of the position occupied by Dr. Loomis in relation to this academy it is recommended that a memorial meeting be held in the hall of the academy on the first Thursday in May, and that the president be requested to invite representative speakers, and take such further action as he may deem appropriate.

Resolved, That a copy of these resolutions be sent to the family of Dr. Loomis, and that they be published in the secular and medical press.

The Brooklyn Death from Diptheria Antitoxine.—Dr. Rosa Englemann, of Chicago, writes to us that she has used with decidedly good results serum from the same lot that included the specimen to which Miss Valentine's death has been attributed.

The Association of the Alumni of the New York Hospital will have its annual dinner at the University Club on Friday evening, the 26th inst.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending March 30, 1895:

Hope, J. S., Assistant Surgeon. Ordered to the U. S. Steamer Montgomery.

Wells, Howard, Surgeon. Detached from the U. S. Steamer Montgomery and granted three months' leave of absence.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending March 30, 1895:

Vaughan, G. T., Passed Assistant Surgeon. To proceed to Philadelphia, Pa., and assume command of service. March 28, 1895.

Cumming, H. S., Assistant Surgeon. To rejoin station, New York, N. Y. March 16, 1895.

Promotion.

Eager, J. M., commissioned as passed assistant surgeon. March 26, 1895.

Society Meetings for the Coming Week:

Monday, April 15th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Cleveland, Ohio, Society of the Medical Sciences; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesday, April 16th: Medical Association of the State of Alabama (first day—Mobile); Medical Society of the State of California (first day—San Francisco); Florida Medical Association (first day—Gainesville); New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Osgenhurst, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Kings, N. Y.; Baltimore Academy of Medicine; Passaic, N. J., County Medical Society (annual).

Wednesday, April 17th: Iowa State Medical Society (first day—Creston); Medical Association of Georgia (first day—Savannah); Medical Association of the State of Alabama (second day); Medical Society of the State of California (second day); Florida Medical Association (second day); Medical-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society; Windham, Conn., County Medical Society (annual—Plainfield); Middlesex, Mass., South District Medical Society (annual—Waltham).
Letters to the Editor.

A WARNING.

42 West 30th Street, New York, April 11, 1895. To the Editor of the New York Medical Journal:

Sir: I wish to call attention to a clever scoundrel who is collecting subscriptions for himself and family on the supposed recommendation of Dr. Howard A. Kelly, of Baltimore. The letter which he presents is a forgery, as Dr. Kelly informs me by telegraph to day. Attached to the letter are several subscriptions from prominent members of the profession in this city. His story is that he left Birmingham, England, three years ago and settled in Baltimore to practice abdominal surgery there. He claims to be an intimate friend of Lawson Tait, with whom he says he is in frequent correspondence; in fact, had a letter from him only a few days ago, in which Tait advises him to return to England, and promises him work again in Birmingham. He had failed to obtain the success in Baltimore that he had good reason to expect, and now asks for a little help to enable him to return to England.

Dr. Kelly’s forged letter recommends him warmly as worthy of assistance. When I asked him if it had not occurred to him that coming from England to practice abdominal surgery in this country was very much like carrying coals to Newcastle, he modestly replied that I was quite right; he had made a mistake, and had been misled by American medical tourists, who had given him glowing accounts of the success of abdominal surgeons in this country. The man was shabbily dressed, redolent of whisky and tobacco, and was evidently a medical tramp on a rapid descent to Avernum. If any one of your readers to whom he presents his forged letter will retain possession of it, send for a policeman at once, and then notify me, Dr. Kelly and I will see that he gets his punishment.

A. Brayton Ball, M.D.

Objections to the Antitoxine Treatment of Diphtheria.

New York, April 10, 1895.

To the Editor of the New York Medical Journal:

Sir: Those that heard Dr. Winter’s very comprehensive criticism of the value of antitoxine serum in diphtheria, at the meeting of the Academy of Medicine on the 4th inst., can not but feel that an important factor has been overlooked in the consideration of the treatment of diphtheria with this substance; and that factor is the globulical power of alien serum on the blood of an animal into which it is injected.

In a monograph on Transfusion of the Blood, published in 1875, L. Landais reported that the serum of the dog, the horse, or the rabbit dissolved the red globulins of other animals with great rapidity; and in the last edition of Professor Stirling’s translation of Landais’s Physiology there is the statement that, if the serum of one animal is transfused into an animal of another species, the blood-corpuscles of the recipient are dissolved, and if there is a general dissolution of the corpuscles death may occur.

Dr. G. Darenberg (Archives de méd. exp., 1892) stated that his experiments showed that, while the serum of an animal of one species did not destroy the red corpuscles of an animal of the same species, it rapidly destroyed the corpuscles of an animal of another species. If warmed to from 122° to 146° F., or exposed to the light for several days, the serum lost this globulical power.

G. Hayem, in his monograph on The Blood, states that the serum of the ox more or less profoundly changes the blood of the dog, producing in it small emboli that may involve the functions of organs or even life itself. Microscopically, these emboli consist of degenerated elements of the blood, the hematoïasts and the red and white corpuscles being altered by the serum. He specifically states that horse’s serum produces phenomena similar to those caused by ox’s serum. He further states that the urine is habitually suppressed and the kidneys are congested.

The tendency of alien serum to produce emboli has also been noted by C. Lortet (La France méd., 1891), who found that if the serum of a dog was mixed with the blood of a man, or vice versa, there were produced more or less pronounced alterations, and solid concretions were formed from the metamorphosed elements.

The undersigned believes that it was this tendency of alien serum to form emboli that caused the death of the seventeen-year-old girl in Brooklyn. And this toxic influence of serum per se explains all the annual and untoward phenomena that have been reported in diphtheria patients treated by antitoxine serum. The post-mortem lesions found in the five-year-old child whose clinical history is reported in the British Medical
Experiences in the Production and Use of Diphtheria Antitoxine.—Dr. Hermann M. Biggs read a paper with this title. He divided the cases treated into two classes—those treated in the Willard Parker Hospital and those treated by the health board physicians in the tenements. The latter series included 253 cases with 40 deaths, a mortality of 15.85 per cent. Of these, 50 had been mild, 96 severe, 42 severe and septic, and the rest of moderate severity. The notes of 252 cases showed that the larynx alone had been involved in 21, and the pharynx or tonsils or both in 116. The pharynx or nares or both had been involved in 57, the larynx or pharynx in 41, and the larynx, pharynx, and nares in 17. Of the 40 deaths, 15 had occurred within twelve hours after the first injection; therefore, excluding these, the mortality had been reduced to 10.4 per cent. All the patients who had died, with one exception, had had laryngeal diphtheria. In 197 cases the antitoxine treatment had been begun before the fifth day, and in these the mortality had been 7.79 per cent. The series of hospital cases, on account of their great severity, and their coming under observation late in the disease, had not yielded such good results. There had been 129 of these cases, of which 83 had been nasal or pharyngeal or both, and 46 laryngeal. In the whole series there had been 31 deaths, or a little over twenty-four per cent. In 1894, during the same season of the year, the mortality in the hospital among 146 similar cases treated without antitoxine had been thirty-two per cent. Excluding 5 of the laryngeal cases treated on the fifth day or later, there had been 19 intubation cases, with 9 deaths. In 1894 there had been 16 intubation cases, with 13 deaths. Out of the 29 patients with laryngeal diphtheria treated with the serum, but not intubated, 6 had died. In a series of 82 cases treated by Dr. Walter F. Benzl, there had been 70 recoveries and 12 deaths, a mortality of fifteen per cent. In 16 of these cases no benefit had been observed from the antitoxine treatment, and in 6 the improvement had been slow in manifesting itself. Thirty-three of the patients had shown no after-effects, but in a considerable proportion an eruption of urticaria had developed in from three to ten days after the injection of the serum. In one case this eruption had been accompanied by intolerable itching and followed by painful swelling of the larger joints and loss of power in many of the muscles. There had usually been a trace of albumin in the urine during these complications. In the fatal cases, no new anatomical lesions had been observed, and there had been no evidence in any case that the antitoxine had produced or hastened the fatal termination. Nearly all the patients had been treated with the serum produced under the direction of the Health Department.

The author said that all that the diphtheria antitoxine could be expected to do was to act as a specific against diphtheria toxemia; it was unreasonable to expect it to restore heart fibers or renal cells that had already undergone degeneration or to ward off impending asphyxiation due to laryngeal stenosis. The earlier it was administered, the better the results. Its value was best attested by the fact that the mortality among patients treated through the city without antitoxine had been between twenty-five and thirty-five per cent, at the same time that those under the antitoxine treatment had exhibited only a mortality of eight or ten per cent.

The Technique of the Production of Diphtheria Antitoxine.—Dr. W. H. Peck read a paper on this subject. He said that it was necessary to have very virulent diphtheria bacilli if one desired to obtain the toxine. Experiments had been made in the laboratory to increase the virulence of the bacilli by passing them through guinea-pigs, but the result of this process had not been very striking. It had been found that the bacilli would grow sufficiently well in ordinary flasks plugged with cotton, but that from two to four weeks were required for the production of the toxine. The strength of a given sample of toxine and the existence of any contamination were determined by experimental cultures made from time to time.

Great care was taken to select horses free from glanders. If the horse reacted well to the first injection of toxine, this was not repeated until the fever and swelling had subsided. After a period of from two to four months a horse was capable of receiving at a single dose one hundred cubic centimetres of strong toxine without exhibiting any marked reaction. There was a great difference in the quantity of toxine furnished by different horses. The blood was obtained by thrusting a glass cannula into the jugular vein, and it was then conducted through rubber tubing into a sterile flask the month of which was carefully protected by sterilized cotton. When the red corpuscles had settled, the clear serum could be decanted readily. After several months the animals became as susceptible to the injection as at first.

Experiences in the Use of Diphtheria Antitoxine for Immunization.—Dr. C. H. Peck read a paper embodying the results of his observations at the New York Infant Asylum on the use of the serum to confer immunity. He said that there had been a hundred and thirty-six cases of diphtheria since September 5, 1894, and that attempts to check the epidemic by quaran-tine measures had proved unavailing. On December 12th forty-two children had been separated from the others, and the antitoxine given to half of this number. No case of diphtheria had developed among them for a month. On January 16th and 17th two hundred and twenty-four children had been inoculated with Behring's antitoxine No. 2, and no case of diphtheria had appeared among these children until February 5th. On February 27th and 28th, two hundred and forty-five children had been inoculated with the board of health's serum, and this had been followed by immunity for a little over a month.

The Results of Autopsies on Persons Dying after Treatment with Diphtheria Antitoxine.—In a paper thus entitled
Dr. George P. Biggs said he had made eighteen such autopsies at the Willard Parker Hospital. The diphtheritic membrane had usually been found quite thin and loosely attached. Par- enchymatous and fatty degeneration of the heart, liver, and kidneys had been very noticeable in most of the cases, and, as it had appeared to be more advanced the later the patients had come under treatment, it would seem that the antitoxine exer- cised a marked controlling influence over such degenerations. False membrane had been found in the small bronchi in only one case. There had been acute fibrinous pleuritis in two of the cases. The spleen had usually been found congested, but not specially enlarged. There had been many cases of exten- sive broncho-pneumonia.

The Anatomical Lesions found in Animals which have Died during the Process of Immunization.—Dr. Ira van Groen read a paper with this title. Taking one of the cases as a type of all, he said that the heart had appeared on gross ex- amination to be normal; the right lung had contained a throm- bus; the abdominal cavity and peritoneum had been normal; the spleen had been softened and congested; the liver and pan- creas had been normal; the cortices of the kidney had been streaked with yellowish-white bands. The lymph nodes had been diseased in all the animals. A most minute examination had been made of the tissues of this animal, with the result of showing the central nervous system normal; the heart muscle very fatty; thrombi of the usual structure in the pulmonary veins; the spleen converted into a mass of blood cells and pig- ment; the liver excessively active; the lymph nodules enormous ly enlarged, and the kidneys showing acute degeneration. From this investigation he was disposed to think that antitox- ine was largely a secretion of the liver cells.

The discussion of these papers was opened by Dr. Joseph E. Winters, who said that some months before he had shared with his colleagues the hope that a specific against the toxines of the diphtheria bacillus had been discovered, but three months of daily observation in the Willard Parker Hospital had been a sad—an extremely sad—disappointment to him, and he regretted to say that, as a result of that experience, he was now present to speak in opposition to the antitoxine treatment of diphtheria. His remarks would be based entirely on three months' daily clinical observation of the effects of the antitoxine in a hundred and fifty-four cases of diphtheria treated in the Willard Parker Hospital. In the first paper of the evening reference had been made to the effects of the antitoxine on the false membrane of diphtheria. What Dr. Winters had to say with reference to this might be best illustrated by referring to four patients that had recently been admitted into the Willard Parker Hospital in the course of one day, as follows:

Case I.—There had been a few patches of false membrane in various portions of the throat, showing that the exudate had already exfoliated, only small portions of it remaining.

Case II.—There had been false membrane on both tonsils, which was thick at the edges, and exfoliation had already be- gun, the membrane being in some places detached from the mucus membrane an eighth of an inch.

Case III.—The patient had been in the early stage of the disease process. The false membrane had been thin at the edges, involving the tonsils and slightly the pillars of the fauces. At one point there had been inflammation at the edge of the false membrane.

Case IV.—This had been a septic case, with an abundance of membrane on the tonsils and the pillars of the fauces and some on the posterior wall of the pharynx.

In Case I, where detachment of the membrane had been nearly complete before the patient was brought to the hospital, the throat had cleared rapidly. In Case II, the exfoliation, which had begun at the time of the patient's admission, had continued, but some membrane had remained on the pillars of the fauces and on the tonsils ten days after admission. In Case III the patient had been free from membrane for the first time on the tenth day after admission. In Case IV, the septic case, the patient had lived three days. During this time, though the pa- tient had been thoroughly under the influence of antitoxine treat- ment, the antitoxine had not made the slightest impression on the symptoms of toxemia. These four cases may be taken as a sample of what the speaker had seen repeatedly at the Willard Parker Hospital during the three months of antitoxine treat- ment of diphtheria. In not a single case had there been the least evidence that the formation of the false membrane had been checked, that its exfoliation had been hastened, or that the throat had been free from membrane earlier than in cases not treated with antitoxine. In not a single septic case had the antitoxine made the least impression on the symptoms. The toxemia had not in one instance been relieved or lessened. There had been no indication in the character or frequency of the pulse or in the general condition of the patient that a spe- cific for the toxemia had been administered.

Reference had next been made in Dr. Biggs's paper to the laryngeal cases of diphtheria, and the speaker would like to ask the author and those who were supporters of the antitoxine treatment why it was that antitoxine should be administered for the relief of the laryngeal stenosis due to a diphtheritic false membrane. While the diphtheritic process remained confined to the laryngeal mucous membrane there was no toxemia. There was, therefore, no indication for the exhibition of an antitoxine. It had been stated in the paper that the death-rate in the laryngeal cases under the antitoxine treatment had been lower than under the methods of treatment in vogue before the use of antitoxine, but Dr. Biggs had compared results observed a year before with the results during the past three months. He had neglected to state that at the Willard Parker Hospital, in the month of December last, there had been eight consecutive recoveries after intubation in cases of laryngeal diphtheria without the use of antitoxine. During the same month at the Foundling Asylum in this city, out of fourteen cases of intuba- tion for laryngeal diphtheria, there had been twelve recoveries without antitoxine. At the Willard Parker Hospital, in the month of December, 1894, the recoveries from laryngeal diph- theria without antitoxine had been about seventy-five per cent. This had never been equalled with the antitoxine treatment with or without intubation.

The paper had dealt largely with statistics. The speaker wondered if the members present had noticed that the author had treated the matter of statistics largely by elimination and exclusion. In comparing the results of antitoxine treatment with the former methods of treatment, in the antitoxine cases he had excluded numerous deaths for one reason or another, while in speaking of the results before the antitoxine treatment no deaths had been eliminated. The facts were that during the first three months of 1894 the death-rate at the Willard Parker Hospital, without antitoxine, had been thirty-two per cent. During the first three months of 1895, with antitoxine treat- ment, the death-rate had been twenty-eight per cent.; but in order to make it clear that this mortality rate did not represent the exact state of things as it should, the speaker would ask his hearers to consider for a few moments the class of cases which had been brought into the Willard Parker Hospital for antitoxine treatment during the past three months. In many of these cases there had been no clinical evidence of diphtheria. They had been cases of diphtheria from the bacteriological standpoint only. Examination of the nose and throat, exami- nation of the constitutional condition of the patient, had re-
vealed no evidence of diphtheria. The patient had had in the throat the Klebs-Loeffler bacillus, but the presence of this bacillus in the throat or in the nose, in the absence of any lesion, was not evidence of the existence of diphtheria.

In passing, he would ask again, Why was antitoxin given in cases in which were diphtheria from a bacteriological standpoint only? It had been proved the world over that antitoxin had no influence on the diphtheria bacillus, it persisted just as long when antitoxin was used as it did when it was not used.

During the first three months of 1894 no case of diphtheria had been seen in the Willard Parker Hospital that had not shown abundant clinical evidence, as well as bacteriological evidence, of diphtheria. These cases of so-called "diphtheria" without any of the clinical manifestations of the disease should have been eliminated from the statistical report, and there had been a score or more of such cases during the past three months. Had these cases been eliminated from the list, the death-rate under antitoxin treatment during January, February, and March would be much higher than it had been during the corresponding months of 1894, and this too, at a time when diphtheria was far milder than it had been a year before. Some of the patients brought into the hospital in February, and many of those admitted in March, were still very ill and would surely die.Were these included, the mortality during the antitoxin treatment would be startlingly high.

The author of the paper, like all others who had written in favor of the antitoxin treatment of diphtheria, had insisted upon early treatment as a sine qua non for the best results, but the record from which Dr. Biggs had prepared his paper would show that the first two patients on the list who had recovered had had their first injection of antitoxin on the eighth and sixth days respectively.

In the next seven cases on the list, the first injection had been given on the fourth day in two cases, on the fifth day in two cases, on the third day in two cases, on the sixth day in one case, and all the patients had died. In Case XXIV on the list, the patient had had the first injection on the ninth day; and had recovered. In one case, with the first injection on the second day, the patient had died. One patient, who had had his first injection on the tenth day, had got well, and one who had had it on the third day had died; and so on throughout the list. It was not the date of the first injection that determined the result, but it was the individual character of the case and the nature of the disease. At the Willard Parker Hospital, in any case which at the time of admission had given evidence that the disease was progressive in its course, that course had not been stayed or changed in any particular by the antitoxin treatment.

It had also been stated that the serum used in the early part of the antitoxin treatment at the Willard Parker Hospital had been so weak that little could be expected from it. A careful study of the record would show that the patients treated with the weaker serum had done better than those treated with the stronger serum. Again, a study of the records would show that those who had had the smaller dose of serum had done better than those who had had a stronger dose. In fact, a careful study of the individual cases of diphtheria treated with the antitoxin in the Willard Parker Hospital would show that there had been no relation between the antitoxin treatment and the recoveries. As to the early treatment of diphtheria with antitoxin, it might be definitely and confidently stated that diphtheria at the present time almost invariably ended in recovery under any method of treatment, if the patient was brought under proper hygienic surroundings and surveillance on the first day of the disease. Diphtheria was hardly ever fatal if the patient was put to bed and properly cared for on the first day of the illness. It was the insidiousness of diphtheria that constituted its greatest danger.

Now, as to some of the untoward or unfavorable effects of the antitoxin treatment, the rashes had been spoken of in the paper and some of the minor features attributable to antitoxine, but the more serious after-effects of the antitoxine treatment had not been alluded to. The speaker would ask his hearers to go with him for the time being to the Willard Parker Hospital and see some of the effects of antitoxine which he had witnessed there. Babies had been brought to that hospital with slight clinical evidence of diphtheria; babies, with the exception of a slight exudate in the throat, and perhaps a slight coarse cough, that were apparently healthy and of a rosy color. They had remained in good condition for perhaps ten days or two weeks after receiving antitoxine; when one day, as you entered the ward, you would hear a moan, and, approaching the crib, you would find the baby lying on its side with its head retracted, with its arms and legs flexed, and moaning piteously. The speaker could best make it clear what this baby's condition was by relating a case about which he had been consulted. A physician had come to his office to advise him regarding his wife. Two weeks previously this lady had had a slight sore throat, and a medical friend had immediately injected her with antitoxine. On the following day it had been decided that she had no diphtheria, but a slight anerydritis, and the throat was all but well. Fifteen days after the injection of antitoxine her temperature had been 105°, her pulse 100, and she had been suffering severe pain in all her joints. Sleep and rest had been absolutely impossible, except by means of large doses of morphia administered hypodermically. This had been a case of antitoxine infection. In this case the antitoxine had been eliminated and the patient had recovered. This was the condition in which the speaker had seen many of the little babies in the Willard Parker Hospital. The temperature chart showed a record of from 105° to 106°, and a note of the night nurse's told that the patient had hardly slept at all. This antitoxine infection pursued one of two courses, either the symptoms gradually subsided, leaving the baby emaciated and extremely anaemic, or there might be a fluctuating temperature, ranging from 99° to 106-8° and existing for days together. What was this condition due to? It was due to the action of the antitoxine on the blood. "Horse serum dissolved human blood-corpuscles, and thereby produced new elements of decomposition. The condition of the babies just spoken of had been one of antitoxin septicaemia, brought about by the influence of the antitoxine on the blood. A further evidence of septicaemia had been seen in occasional suppurations, as in one case in the neck and ear, in another in small points of suppuration in various portions of the body. In these cases there would be a temperature range such as had not been seen in the hospitals of this city since the introduction of septic surgery. This was a temperature range such as had been seen in the surgical and maternity wards of Bellevue Hospital twenty years ago.

It had been said that many of these patients treated with antitoxine had not died of diphtheria; that an autopsy had proved that the babies had recovered from diphtheria, and that the lesions showed that they had died of pneumonia after recovery from diphtheria. This pneumonia in the Willard Parker Hospital during the past three months had come on late in the course of the disease, and it had been such a pneumonia as was seen in Bellevue Hospital when they were having a great deal of septicaemia there. It was the pneumonia of septicaemia, and this septicaemia was induced by antitoxine.

A second form of antitoxine infection had been seen in the case of a little girl, thirteen months old, admitted on March 22d. She had been given the first injection of antitoxine immediately,
The temperature before it being 101.8°. The temperature six hours after the injection had been 104°. The second injection had been given on the 23d, and in the afternoon of the same day the kidneys had ceased to act. The hot pack and other methods of treatment had been resorted to, but the baby had died, in spite of all treatment, on the afternoon of the 29th. Mr. Lennox Brown had reported eight cases of diphtheria treated with antitoxine, and death had resulted in six of them from inflammation of the kidneys. Benda had found nephritis in thirty-three per cent of thirty-nine that had died under the antitoxine treatment.

An instance of antitoxine infection through its action on the nervous centers had occurred in a baby, two years and four months old, admitted on March 19th. The temperature had been 101.8° on admission. The first injection of antitoxine had been given at 6.30 p.m., and the baby had a restless night. At 5 a.m. on the 20th the temperature had been 105°; at 5.45 a.m. the baby had been in convulsions, and had died at seven o'clock in convulsions. Death had resulted in thirteen hours and fifteen minutes after the injection of antitoxine.

The third case of immediate result with antitoxine had been in a baby, eleven months old, admitted on March 29th. The temperature had been 101.8° on admission. The first injection had been given on the day of admission, and the second one on the following day. About twenty-four hours after the admission the baby's temperature had been 105°, and convulsive movements of the eyes had been noticed. Careful examination had revealed no evidence of organic disease. The baby had been in semi-stupor, the respirations twenty-eight to the minute, the pulse rapid, irregular, and intermittent. On March 31st the temperature had been 100.8°, and there had been general convulsions. At 1.30 a.m. on April 1st, the temperature had been 108°, and the baby had died an hour later in convulsions. Autopsies had been asked for in these cases but not granted in any of them. Physical examination had revealed no evidence of organic disease; they had unquestionably been cases of antitoxine poisoning. This brought us to one of the most important considerations in connection with the subject of antitoxine treatment of diphtheria—namely, individual susceptibility to the action of remedies. There was now present a physician who, about a year ago, had come very near dying from the influence of a single dose of one-hundred-and-fiftieth of a grain of atropine. He had been originally healthy and well at the time, with the exception of a slight coryza. Any one in the room might have taken the same dose or double the amount without suffering any ill effects. This was one instance of individual susceptibility. As everybody knew, one person was specially susceptible to the influence of morphine, another to the influence of atropine, and so on throughout the entire list of remedies. So some individuals were specially susceptible to the influence of antitoxine. When this susceptibility existed, or to what extent, could never be known beforehand. It was the existence of this special susceptibility which caused the antitoxine to produce its fatal effects in the cases here enumerated. It was the existence of this special susceptibility or idiosyncrasy in the case of Miss Valentine that had caused her unfortunate death from a single injection of antitoxine. That the antitoxine used in her case had been irrepresensible in every way had been officially certified to by the board of health of this city and that of Brooklyn. The fault had not been in the antitoxine used, but in the special susceptibility of the patient. This same antitoxine might have been used on another person without producing any ill effect. We knew nothing of this individual susceptibility beforehand, and any physician who used antitoxine took the risk of bringing about the results which the speaker had described as having occurred in the Willard Parker Hospital, and the result which had occurred in the case of Miss Valentine. A case parallel to these had been reported in the British Medical Journal for March 24, page 785. A well child, three years old, had been given an immunizing dose of 2 c.c. of No. 1 Behring serum. The next morning the child had been depressed; on the following day she had had fever and violent pain in the lumbar region, and the urine had contained a considerable quantity of albumin; the next day the temperature had been 106° F., and pechice had appeared on the legs; and on the following day the child had died.

In conclusion, the speaker was opposed to the antitoxine treatment of diphtheria, first, because in an experience of one hundred and fifty-four cases during the months of January, February, and March, 1895, in the Willard Parker Hospital, he had failed to see the slightest evidence that it neutralized the toxemia in a single case. He had never found that it exerted the slightest influence for good on a single clinical manifestation of the disease; on membrane, pulse, temperature, gland swelling, laryngeal symptoms, etc. Every one of these patients had been examined daily; they had been examined with care and with great solicitude, and with the desire to discover some evidence of the virtues ascribed to antitoxine by others.

Secondly, he opposed it on account of its immediate danger to life through its influence on the kidneys and on the nervous system and remotely through its influence on the blood.

Dr. George L. Peabody said that it was evident that we had a complicated problem to solve. He also had met with cases showing how exceedingly unsatisfactory a bacteriological diagnosis of diphtheria alone might be. In one case he had taken cultures from the throats of four children and from that of their governess, and had submitted them to an expert bacteriologist for examination. The children's throats had appeared perfectly normal, while there had been a suspicious membrane in the throat of the governess. Strangely enough, the bacteriological report had stated that Locyfler bacilli had been found only in the cultures from the throats of the children. He also knew of an individual in whose throat the bacilli had persisted for three or four months after an attack of diphtheria. These observations would seem to show that the bacilli might be present without diphtheria, but there could be no diphtheria without the bacilli. His experience with the antitoxine had been quite satisfactory, although he had seen one case in which there had been well-marked septic symptoms, such as had been described by Dr. Winters. He was inclined to think that Dr. Winter's bad opinion of the treatment might be explained by supposing that he had been treating "mixed infections." It was not improbable that some of his cases of pneumonia had really been due to streptococci infection.

Dr. L. Emmett Holt said that he had observed the effects of diphtheria antitoxine in about twenty cases. These cases had been in small children in institutions in which the mortality had been about seventy per cent., yet every child injected on the first or second day of the disease, with the exception of a baby suffering from marasmus, had recovered. He would like to protest against the slur made on the bacteriological diagnosis. Systematic examinations of this kind of all children admitted into the Babies' Hospital during the past five months had shown the presence of the Locyfler bacilli in about one third of the children. This only showed that there must be both a clinical and a bacteriological diagnosis.

Dr. W. L. Somerset said that, as intern of the Willard Parker Hospital for the past sixteen months, he had had an opportunity of watching the cases carefully. There had been many irregular changes of temperature, also rashes which had formerly been attributed to some digestive disturbance, but now all these phenomena were charged to the antitoxine. He showed
BOOK NOTICES.

Traité pratique de gynécologie. Par le Dr. A. Auvard, Ac- 
conseiller des hôpitaux de Paris. Deuxième édition, revue 
et augmentée. Avec 655 figures dans le texte et 13 planches 
[Prix, 18 fr.]

Dr. Auvard seems to entertain a generous idea of what 
gynecology should embrace, if we may judge of it by this book, 
for, besides the topics usually considered in gynecological text-
books, he treats of such subjects as the cutaneous and venereal 
diseases of women's genitals, lithotripsy, and impotence and 
sterility in men. This is by no means to be objected to, only 
we wonder why an author with such a broad conception of his 
theme should not have treated also of the diseases of the breast. 
But M. Auvard says at the outset that he restricts his book to 
the subject of the normal condition and the pathological states, 
apart from the puerperium, of the genital apparatus, and employs 
the term gynecology in its present conventional sense. The 
true title of his work, he says, would be Traité de gynécologie 
féminine après la puerpéralité. We think he is to be commended for 
having finally denied himself the pleasure of giving such a name to 
the book. The remainder of the introductory chapter is de-
voted to a sketch of what we may call the evolution of modern 
gynecology, which he briefly defines as consisting of five pe-
riods: 1. The rudimentary (embryonic or vulvar). 2. That of 
the spectrum, the era of Récamier. 3. That of hysterometry, 
when the essence of uterine pathology was held by some to lie 
in engorgement and by others in displacements. 4. The peri-
metrium, in which the uterine annexa figured largely in gynecolo-
gical procedures, and antiseptics had paved the way for a free 
sort to cutting operations. 5. The present period of maturity and 
épo'énuissement, the history of which he thinks it would be 
premature to write at present.

The first chapter deals in a general way with the etiology, 
symptomatology, diagnosis, and prognosis of diseases of the 
by the hospital records that there had been a distinct lowering of 
the mortality rate in the group cases since last year. In 
most autopsies in such cases, he said, there had been adherent 
membrane found below the larynx, whereas in the recent autop-
sies of the group patients that had received the antitoxine 
treatment he had remarked the absence of membrane below the 
larynx.

Dr. Bieso said that any one who would deliberately state 
that there was little severe diphtheria now in New York city 
could not be considered an unbiased observer; at any rate, 
there had been twenty-eight hundred deaths during the past 
year from diphtheria and diphtheria. He wished again to emphasize 
the statement that antitoxine did not neutralize sepsis or 
broncho-pneumonia, but simply diphtheria toxemia. Antitox-
ine was beneficial in group cases by neutralizing the diphtheria 
toxines and reducing the inflammatory swelling. The fact that 
the mortality rate from diphtheria had been suddenly lowered 
all over the world would seem to argue in favor of the value 
of antitoxine. So far as he knew, no case had been included in 
his statistics in which there had not been a clinical as well as a 
bacteriological diagnosis of diphtheria made. The hospital cases 
had invariably been reported to the board of health by some 
practicing physician to be diphtheria. At present every distin-
guished bacteriologist and pathologist of Europe had accepted 
the antitoxine treatment as the most important advance in ther-

Phthisis pulmonum. By Dr. Barlow, F.R.S. London: 
W. H. Allen. 8vo. Pp. 37. [Price, 2s. 6d. net.]

The author in his preface states that he has made 
a careful study of the results of the operation of bronchial 
radium therapy, and from a careful review of the condition of 
the condition of the bronchi, he has come to the conclusion 
that the treatment of this disease by the radium is not 
without danger, and that care should be exercised in 
the employment of the radium. It is not a treatment 
that is without danger, and it is not a treatment that is 
without danger, and it is not a treatment that is without danger, 
and it is not a treatment that is without danger, and it is not a treatment that is without danger, and it is not a treatment that is without danger, 
and it is not a treatment that is without danger, and it is not a treatment that is without danger, 
and it is not a treatment that is without danger, and it is not a treatment that is without danger, 
and it is not a treatment that is without danger.

BOOK NOTICES.

[N. Y. Med. Jour.]

general, the theme is well handled, but we regret to see mention made of anteflexion, for example, of the "first degree" or of the "second degree"; such distinctions we think arbitrary and difficult of definition and therefore confusing. We are sorry, too, that the author approves of the elastic ring pessary.

Succeeding chapters deal with inversion of the uterus, pelvic haemorrhage (with a consideration of the subject of extraperitoneal haemorrhage in cancer), and tumors. We are glad to find in the last-mentioned chapter an excellent section on the palliative treatment of cancer, for the authors of gynaecological text-books are too apt to slur over this very important matter. There will always be many cases that are "inoperable" for one reason or another, and the fact that they promise no addition to the surgeon's laurels as an operator can not justify inattention to them on his part. On page 532 there is an ingenious chart contrasting the course of normal menstruation with various types of menorrhagia and intermenstrual haemorrhage due to uterine fibroids. The electrical treatment of these tumors, as taught by Tripler and Apostoli, M. Auvard regards as in the highest degree palliative and, when carefully employed, free from danger, but he does not think it is ever really curative. He attaches much importance to its moral effect on patients who utterly refuse to submit to more radical procedures—bistouriphobic, as he calls them.

The next chapters are on menstrual disorders, on sterility, and on affections of the urinary tract. We do not understand what M. Auvard means by uterine urethrotomy (uretrotomie utérine), which he mentions, on page 687, as one of the procedures to which recourse may be had in the treatment of urethral strictures. Twice, on page 708, the author makes the statement that suprapubic cystotomy is much more difficult to perform on women than on men, but he does not specify wherein the difficulty lies, and we are inclined to think that in this matter he is in error.

Diseases of the rectum and anus, tumors of the pelvic bones, and pelvic neuralgia are the topics discussed in the next chapter. Then comes a chapter on abdominal affections simulating disease of the genital apparatus (the author's abdominopathies simili genitales, before mentioned), containing a valuable section on "mechanical dyspepsia," that is to say, dyspepsia due to ptosis of some abdominal or pelvic organ, a subject to which attention has been ably drawn by M. Gélineau. The book concludes with a short chapter on diagnosis.

We have remarked upon certain grotesque words employed by M. Auvard; in addition, we have noted a number of errors of expression. In the first place, throughout the book, so far as we have observed, whenever a Greek word is brought in, it is without accent or breathing, and a more glaring error in Greek is the appearance of ραμφορος for Ερυμφορος. The word "coecum" appears several times instead of coeexus. Among misspelled proper names, we notice Lacas Championnière and Neugebauer. The bad practice of making several proper names strung together do duty as substantives is exemplified in the expressions procédé de Richetot Bjugard and opération d'Atgique Alexander-Adams. A gross misuse of words—one that, unfortunately, is exceedingly common in medical writings—is shown in the phrase rupture . . . d'une grossesse (page 471), intended to mean, not rupture of a pregnancy, but of a gestation sac.

Almost all the illustrations, whether chromolithographs or woodcuts, are coarse and inaccurate. It must be said, however, that one of the two cuts representing the Sims posture—the one on page 17—comes nearer to being a true representation of that posture than most of the cuts that have been published. On pages 306 and 307 there are three cuts to show operative procedures facilitated by extreme antero-posterior
distention of the vaginal orifice by means of two retractors; yet the outline of the side of the vulva, instead of running tant from one instrument to the other, sweeps outward in great amplitude and laxity. The pyramid of ring pessaries shown on page 379 is such a picture as we should hardly expect to find elsewhere than in an instrument-maker's catalogue. Wherever the clitoris is figured in sagittal section, it is of great size and looks like a tracheotomy tube just ready to drop out.

The defects we have pointed out are not of the first magnitude, and we do not think they seriously detract from the value of the work, which is great. It is a book that every gynaecologist may study to advantage.

We infer that this is the first of several volumes to complete a system. As its title indicates, the book is devoted to the broad principles and pathological developments which underlie all scientific surgical practice. It is intended as a foundation upon which the student may rear the edifice of practical surgery.

The indications for an operation in general, and the discussion of the preparations for an aseptic operation, form an interesting opening chapter, which, if mastered by the student, will render him an efficient aid in the operating room early in his career. Further on, the author goes over the general rules for aseptic and antiseptic operations in a most thorough and scientific manner. Why these chapters should have been separated we fail to perceive.

In the chapter on alleviation of pain during operations the author's preference for chloroform over ether is clearly manifest. Twenty-three pages are devoted to the former, while less than three are given up to the latter, and in these there occurs the remarkable statement "the action of the drug is not so lasting" as that of chloroform.

In future editions this misstatement should be left out. On page 45 credit is given to Dr. Wagner and Dr. Herzog in the conjoined use of cocaine with the galvamic current to which, we believe, Dr. Corning, of New York, is entitled.

The second section of the work is devoted to the methods of applying surgical dressings. The first chapter in this section on antiseptic and aseptic protective dressings, is almost beyond criticism. It is worth the price of the book. The chapters on bandaging and surgical appliances are disappointing, and not to be compared with those in some of our American surgeries.

The third section is devoted to surgical pathology and therapy. Here are discussed the various inflammations and injuries of the different tissues of the body in a most thorough and interesting manner. The morphology and significance of micro-organisms, the infectious wound diseases, and the specific bacterial or microbic affections which generally come under the care of surgeons are grouped together, and the latest theories and treatment of them given. The space devoted to some of them would seem inadequate were it not that they only remotely relate to surgery and belong more properly to other branches of medicine.

Much of the chapters on injuries and diseases of the bones
and joints will have to be repeated in the volumes on regional surgery, for it is impossible to discuss specific lesions without referring to these general principles. The concluding section, on tumors, is the most succinct and satisfactory résumé of the subject that we know of.

As an introduction to the study of surgery this is indeed a useful book.

Notes on the Newer Remedies. Their Therapeutic Applications and Modes of Administration. By David Cerna, M. D., Ph. D., Demonstrator of Physiology and Lecturer on the History of Medicine in the Medical Department of the University of Texas, etc. Second Edition, enlarged and revised. Philadelphia: W. B. Saunders, 1895. Pp. 11 to 253. [Price, $1.25.]

The appearance of this new edition of Dr. Cerna's very valuable work shows that it is properly appreciated. The author must have done an immense amount of reading to obtain the data that he has condensed within so small a compass, and it is evident that his reading has been critical. The book ought to be in the possession of every practicing physician.

It is difficult to add anything to what has already been said regarding the first and second parts of this work. Taken together, the collection of superb plates will form a beautiful addition to an anatomist's library.

BOOKS, ETC., RECEIVED.

Text-book of Diseases of the Kidneys and Urinary Organs. By Professor Dr. Paul Förbringer, Director of the Friedrichshain Hospital, Berlin, etc. Translated from the German with Annotations by W. H. Gilbert, M. D., Physician in Baden-Baden, etc. With Commentatory Letter from Sir Thomas Grainger Stewart, M. D., F. R. S. E., Physician in Ordinary to H. M. the Queen, for Scotland, etc. In Two Volumes. Vol. I. London: H. K. Lewis, 1895. Pp. 194.

Maliades congénitales du coeur. Par A. Monsson, professeur agréé à la Faculté de médecine de Bordeaux, etc. Paris: G. Masson, 1895. Pp. 5 to 238. [Encyclopédie scientifique des aide-mémoire.]

Memorabilia. Zeitschrift für rationelle praktische Aerzte. In Verbindung mit Dr. Guido Bell, Indiamolis, Privatarmat Dr. E. Boek, Liebau, Dr. W. Günther, Regierungs-Rath und Professor in Salzburg, etc. Herausgegeben und redigirt von Dr. Friedrich Betz, praktischer Arzt in Heilbronn a. N. XXXXIX. Jahrgang. I. Heft. (Neue Folge, XIV. Jahrgang.) Heilbronn: Albert Scheuren, 1895. Pp. 64.

Transactions of the Obstetrical Society of London. Vol. XXXVI. For the Year 1894. Part IV for October, November, and December.

Report of the Commissioner of Education for the Year 1891 to 1892. Volume I, containing Part I. Volume II, containing Parts II and III.

Eight Annual Report of St. Margaret's Hospital of Kansas City, Kansas.

Infection and Immunity, with Special Reference to the New Diphtheria Antitoxine. By Charles Russell Bardeen, B. A., Baltimore. [Reprinted from the School Bulletin.]

Consideration of some of the Indications for Operation in Head Injuries. By William N. Bullard, M. D., Boston. [Reprinted from the Boston Medical and Surgical Journal.]

Cerebellar Tumor. Operation; Hemorrhage from Defect of Occipital Bone; Death; General Remarks. By W. N. Bullard, M. D., and E. H. Bradford, M. D. [Reprinted from the Boston Medical and Surgical Journal.]

Colliquoyia for Puerperal Septicemia and Peritonitis. By Charles P. Noble, M. D., Philadelphia. [Reprinted from the American Gynecological and Obstetrical Journal.]

The Results obtained from the Use of Aniline Products in the Treatment of Cereinoma. By Willy Meyer, M. D. [Reprinted from the Annals of Surgery.]

Recent Methods of Gastrostomy for Stricture of the Stomach. By Willy Meyer, M. D. [Reprinted from the American Journal of the Medical Sciences.]

An Improved Method of the Radical Operation for Carcinoma of the Breast. By Willy Meyer, M. D. [Reprinted from the Medical Record.]

Modern Surgery of the Pelvic Floor in Women. By George H. Kirwan, M. D. [Reprinted from the American Gynecological and Obstetrical Journal.]

Vaginal Hysterectomy as done in France. By Edgar Garceau, M. D., Boston. [Reprinted from the American Journal of Obstetrics.]

Complications of Vaccination. By Louis Frank, M. D., Milwaukee. [Reprinted from the Journal of the Cutaneous and Genito-urinary Diseases.]

MISCELLANY.

The Study of Anatomy and Pathology in New Jersey.
—The text of a new law of the State of New Jersey, "to provide for the incorporation of pathological and anatomical associations for the advancement of medical and surgical science," is as follows:

1. Be it enacted by the Senate and General Assembly of the State of New Jersey, That any three or more physicians duly authorized and licensed to practice medicine under the laws of the State of New Jersey, who shall desire to associate themselves together for the purpose of pathological and anatomical study and the advancement of medical and surgical science may make, record, and file a certificate in writing in manner hereinafter mentioned.

2. And be it enacted, That such certificate in writing shall set forth:

1. The name or title assumed to designate such association; II. The place or places in this State where the purposes of such association are to be carried out; III. The purposes for which the association shall be formed; IV. The names of the governors or directors who shall manage its affairs for the first year of its existence.

3. And be it enacted, That such certificate shall be proved or acknowledged and recorded, as is required of deeds of real estate, in a book to be kept for the recording of certificates of incorporation in the office of the clerk of the county where the purposes of such association are to be carried out, and after being so recorded shall be filed in the office of the secretary of state; the said certificate, or a copy thereof, duly certified by said clerk or secretary, shall be evidence in all courts or places.

4. And be it enacted, That upon making such certificate and causing the same to be recorded and filed as aforesaid, the said physicians so associating, their successors and assigns, shall, by virtue of this act, be a body politic and corporate in fact and in law, by the name stated in such certificate, and by that name they and their successors shall have perpetual succession and power to sue and to be sued, plead and be implored, answer and be answered unto, in all courts and places whatsoever, to make and use a common seal, and the same to use at pleasure and take, hold, receive and enjoy any lands, tenements or hereditaments in fee simple or otherwise, and any goods, chattels or property of any description, real or personal, and whether acquired by gift, grant, devise, bequest or otherwise, and the same to grant, convey, lease, assign, sell or otherwise dispose of for the purposes of said association.

5. And be it enacted, That the directors or governors of such association shall have power from time to time to make, alter and amend by-laws not inconsistent with the constitution of the United States or of this State, fixing or altering the number of its governors or directors for the management of its property and the regulation and government of its affairs and providing for the mode of filling vacancies in and removing any member from their number and prescribing qualifications for membership of the association and to appoint such agents and officers as shall in their judgment tend to promote or advance any purpose of the association and to prescribe their respective duties.

6. And be it enacted, That no governor or director of any association organized under this act shall receive, directly or indirectly, any salary or emoluments from such association, nor shall any compensation whatever be voted, allowed or paid by the governors or directors thereof, to any governor or director for services, either as governor or director, or in any other capacity.

7. And be it enacted, That the property of any association organized under this act and held for its purposes to an amount not exceeding five thousand dollars shall not be liable to the imposition of any taxes.

8. And be it enacted, That whenever an association shall be formed or organized under this act in any county of this State, all public officers, agents, and servants, and all officers, agents, and servants of any such county or of any city, township, borough, district, and other municipal and of any and every almshouse, prison, morgue, hospital, or other public institution in such county, having charge or control over dead human bodies, required to be buried at the public expense, are hereby required to notify the president or other head officer of any such association or such person or persons as may, from time to time, be designated by said association as its duly authorized officer or agent, whenever any such body or bodies come to his or their possession or control, and shall, if such association or its duly authorized officer or agent request it, without fee or reward, deliver such body or bodies, and permit such association and its duly authorized officers or agents, who may comply with the provisions of this act, to take and remove all such bodies, to be used within this State for the advancement of medical and surgical science; but no such notice need be given, nor shall any such body be delivered, if any person claiming to be, and satisfying the authorities in charge of said body that he or she is, of kindred or is related by marriage to the deceased, shall claim the said body for burial, but it shall be surrendered for interment; nor shall the notice be given or body delivered, if such deceased person was a traveler who died suddenly, in which case the said body shall be buried.

9. And be it enacted, That the said association may employ a carrier or carriers for the conveyance of said bodies, which shall be well inclosed within a suitable casket or case and carefully deposited free from public observation; the drivers or persons in charge of such carrier or carriers shall obtain receipts by name, or, if the person be unknown, by a description of each body delivered by him, and shall deposit said receipts with the person or persons in charge of the institution from which the said body was taken.

10. And be it enacted, That no association organized under this act shall be allowed or permitted to receive any such body or bodies until a bond shall have been given to the State of New Jersey by the said association, with two or more sureties, to be approved by the clerk of the court of common pleas of the county in which such association shall be organized, and shall be filed with the said clerk of said court, which bond shall be in the penal sum of one thousand dollars, conditioned that all such bodies which the said association shall receive shall be used only for the promotion of medical and surgical science within this State; and whosoever shall sell or buy such body or bodies, or in any way traffic in the same, or shall transmit or convey, or cause or procure to be transmitted or conveyed, said body or bodies to any place outside this State, shall be deemed guilty of a misdemeanor, and shall, on conviction thereof, be punished by a fine not exceeding two hundred dollars or be imprisoned at hard labor for a term not exceeding one year, or both, at the discretion of the court.

11. And be it enacted, That neither the State nor any county or municipality, nor any officer, agent, or servant thereof, shall be at any expense by reason of the delivery or distribution of any such body or bodies, but all the expense thereof shall be paid by the association receiving said body or bodies.

12. And be it enacted, That whenever more than one association shall be organized under this act within the same county it shall become the duty of the board of governors or directors of each association so as aforesaid organized within the same county to appoint two of their own number, who together shall constitute a board of distribution of dead human bodies, subject
to delivery to such associations under the provisions of this act, which board of distribution shall be notified, as provided in the eighth section of this act, whenever any body or bodies may be subject to delivery under the provisions of this act, and it shall be the duty of said board of distribution to distribute the bodies which may from time to time be so delivered to it under the provisions of this act equally and in just rotation among the different associations organized under this act.

13. _And be it enacted,_ That it shall be lawful for any association organized under this act to apply for and to receive from any county in this State dead human bodies, which may be required to be buried at the public expense and which shall not be claimed by any individual or relation, as provided in the eighth section of this act, and it shall be lawful for any public officer or agent or any person in charge of a public institution as enumerated and set forth in the eighth section of this act, to deliver such human body or bodies under the restriction of said eighth section of this act, to any association organized under this act in any county in this State; provided, however, that when any such association shall have been organized in any county, no body or bodies shall be removed to another county without the association or associations within said county having had an opportunity to receive said body or bodies.

14. _And be it enacted,_ That any person having duties enjoined upon him by the provisions of this act who shall neglect, refuse, or omit to perform the same as hereinbefore required, shall, on conviction thereof, be liable to fine of not less than ten dollars nor more than one hundred dollars for each offense.

15. _And be it enacted,_ That all acts and parts of acts inconsistent with this act be and the same are hereby repealed.

16. _And be it enacted,_ That this act shall take effect immediately.

**Phlebitis Due to Grippus.**—In the _Nouveau Montpellier Medical_ for March 9th there is an article on this subject by M. Estor, who remarks that, owing to its many complications, the grippe belongs to surgery as well as to medicine. This infectious pyrexia, he says, often gives rise to moderate ophritis, and it becomes localized in the articulations, producing the arthropy that so commonly is seen in microbicial diseases. Occasionally it causes suppuration of the pleura. The circulatory system is sometimes involved and may present a more or less profound alteration after the disease has run its course. The heart, the arteries, and the veins may be attacked, and gangral gangrene following arterial lesions has been observed. Venous thrombosis is a complication which, without being very rare, says M. Estor, is certainly not frequent.

Phlebitis was observed during the first epidemic of 1889, and in 1890 M. Laveran reported to the _Société de Biologie_ that phlebitis was a frequent complication. The venous complications were observed not only in Paris, but in Marseilles and in Lyons. M. Teissier, in his remarkable work on grips, described phlebitis in the chapter on grips complications, referred to twenty-five cases that had been published, and presented five personal observations. Brauot, Troisier, Legendre, and others observed similar cases, and M. Renda observed several cases, among which the following seemed particularly interesting to the author: The patient had recovered from an attack of grippal broncho-pneumonia when thrombosis of the primitive liga arteries supervened, and this was followed by gangrene of the legs. At the autopsy, in addition to the arterial lesions, the femoral vein was found to be obliterated at the level of Scarpa's triangle by a clot measuring about five centimetres in length which contained pneumoocci and furnished fertile cultures.

Not every phlebitis, says the author, that appears at a more or less remote time from the onset of the disease should be considered, in reality, as being grippal in its nature. In order that the facts may be convincing, it is necessary that the relation between phlebitis and grippe should not be open to doubt, and that grippal infection alone may explain the cause of phlebitis. M. Estor relates the histories of several cases which had come under his personal observation, of which the following are the most important: The first case was that of a man, fifty one years old, who was in good health and had no varicose veins. On January 4, 1890, he was attacked with grippal broncho-pneumonia, and ten days later, after the bronchitis had disappeared, pains set in in the calf of the right leg and finally spread to the thigh. This was the beginning of phlebitis of the deep veins, which persisted for three months, and for five or six months afterward the leg became swollen on the least exertion. In December, 1894, the same patient had a second attack of bronchitis, and eight days after the onset of the disease phlebitis of the deep veins of the right leg appeared, and at the time of the report the patient had not recovered. The second case was that of a man, fifty-three years old, on whom the author had performed an operation for fistula in ano in December, 1894. The fistula had been extensively cut, and there had been no suppuration, and the patient had been entirely cured when, on the 15th of January, very distinct symptoms of grippal infection appeared, and pleuro-pulmonary congestion of the right side set in, which disappeared quickly, however, under the influence of the treatment, and the patient had apparently recovered when he complained of pains and swelling in the left leg; there was no cordlike induration in the situation of the internal saphenous vein. Absolute rest was prescribed, but on the 5th of February the patient, while making a sudden effort, died at once.

The existence of grippal phlebitis, says M. Estor, appears to be established by indisputable facts; moreover, the study of infectious diseases induces us to admit the nature of this phlebitis, and we really know that venous complications are not rare in microbicial diseases. In typhoid fever particularly, Bouilland, Chomel, and Trousson for a long time observed the appearance of phlebitis. Outinel's and Vaquer's works confirm these observations, and all agree that it is at the decline of the fever that phlegmacea appears, and it is also at the decline of grippal that phlebitis shows itself, and, in all cases, when the patient appears to be entirely cured. Sometimes it is the fifteenth day, sometimes the tenth or the twenty-fifth, according to the gravity of the initial infection. Thrombosis has also been observed in eight cases as well as in serious ones. It is very perplexing, says the author, to discover the causes of the grippal infection in the veins. The patients in the cases described, and in the majority of others, were healthy persons without atheroma or varicose troubles. Vaquer maintains that grippal phlebitis attacks especially those who are exhausted by other affections, such as cachexia, cancer, chlorosis, etc., but the author's observations do not confirm this opinion.

Phlebitis always attacks the same place, and it is invariably in the veins of the legs that the disease becomes localized. Sometimes it is the superficial blood-vessels, sometimes the deep ones that are invaded. Authors, says M. Estor, have been careful to point out that palpation did not reveal a cordlike induration on the inner surface of the leg, and that the patients complained of pain at the fold of the groin and in the hollow of the popliteal region, and they have rightly concluded that it was the deep veins that were attacked. In several cases phlebitis was bilateral, but the legs were not generally attacked at the same time.
Apart from this information as to the seat of the disease, the author says, we learn little from pathological anatomy, for autopsies are very rare, and in nearly all cases the termination is favorable.

Pain is the first symptom, and sometimes, in cases of superficial phlebitis, it is found along the course of the internal saphenous vein; at other times, and more frequently when it attacks the deep veins, it involves the muscles of the calf of the leg, the popliteal vein, and the fold of the groin. Characteristic edema occurs afterward, the duration of which is variable. The swelling always persists for a month, and often three months, after which it entirely disappears. Disorders of the sensibility may be observed occasionally, and a rather marked unsensory atrophy has been noted, which is explained not only by the enforced rest, but also by the phlebitic alterations of the vasa nervorum.

M. Estor remarks that he has called attention anew to this complication of grippé in order that physicians may carefully watch their patients during the decline of grippé and prescribe absolute rest as soon as slight pain or edema appears in the leg.

The same journal publishes a report of a recent meeting of the Société de médecine et de chirurgie pratiques, of Montpellier, at which there was a discussion on this subject in which M. Tédeanat remarked that one of the cases reported by M. Estor was not conclusive, as the patient had had varices. This, he said, did not prove, of course, that there had been no well-established cases of gríppé phlebitis; nevertheless, it was necessary to be very careful and to take into consideration the phlebitis which had been due to other infectious diseases.

M. Forgue remarked that rheumatic phlebitis had also existed, and he asked M. Estor if, in the cases referred to, rheumatism had not been present. M. Estor replied that there had been nothing of the sort. M. Tédeanat related the case of a patient who had presented arterization of the internal saphenous vein after an attack of erysipelas. M. Hanzier had seen a syphilitic patient who had presented a tumefaction in the suprarenal region of the thigh, and the saphenous vein had been found to be very hard.

The Artificial Feeding of Infants.—In the Revue internationale de médecine et de chirurgie pratiques for March 25th there is an abstract of an article by M. Laskine which was published in the Gazette des hôpitaux for January 25th. This question, says the writer, is one of great interest to the physician and especially to the obstetrician. Frequently, for many reasons, natural nursing is impossible, and among the rich a wet-nurse may always be employed, but among the poor artificial feeding becomes a necessity. Under some circumstances the child may be nursed directly from an animal, and it is in this way that goats, sheep, and asses have been used. In large cities it is customary to have a sufficient quantity of milk for the day left at the house, and the milk from one cow is often set aside for the child's use. This practice, says the writer, is condemned by authors who have studied the question. Trouseau advises mixing the milk from different cows, and more recently Gaertlec and Brüecke advised the same practice, thinking that in this way the noxious influence of contaminated milk might be lessened. The author has investigated various methods of preserving milk for artificial nursing, and after having tested the effect of cold, of boiling, and of alkalinization, he expressly recommends sterilization. With regard to sterilized milk being easily digested, he says, there are many opinions, but experiments have shown that it is as easily digested as fresh or boiled milk. With regard to diluting the sterilized milk, those who are in favor of doing so advance the follow-

ing arguments: Cow's milk is different in composition from woman's milk; besides, boiling the milk causes it to become more concentrated, and in this condition it is often difficult of digestion. Other authors do not accept this theory. According to Parrot, Galantin, and Ferron, dilution does not change the properties or the reciprocal proportions of all the component parts, and the water may be a source of infection.

This divergence of opinion, says the writer, shows that there is no fixed rule, and that, when it is necessary, the milk should be diluted according to its richness, and especially with regard to the way in which the child tolerates it. The water should previously be boiled and filtered.

Notwithstanding the success which has been used as an argument in favor of sterilized milk, the writer thinks with M. Budin and M. Laskine that no artificial food should be substituted for the mother's milk unless it is absolutely necessary, in which case sterilized milk should be given the preference.

The Cataphoric Application of Hydrogen Dioxide.—In an editorial in the April number of the Dental Cosmos the writer, referring to the therapeutic application of the electric current, says that a number of experiments have shown that certain medicines when topically applied may be driven into the subjacent tissue by the electric current. That absorption of drugs by this method has been greatly aided, and their effect enhanced, has been proved, he says, beyond a doubt. An interesting adaptation of the cataphoric method in bleaching discolored teeth is as follows: The tooth to be bleached is prepared and desiccated, with the rubber dam adjusted in the same way as in ordinary bleaching operations. A pledget of cotton saturated with a twenty-five-per-cent. solution of pyrozone is introduced into the pulp-chamber, the canal, and the cavity of decay, and the positive pole of a battery of low tension, furnished with a needle-like platinum electrode, is put in contact with the pyrozone. The negative electrode may be held in the patient's hand, or when mounted with a suitable point may be applied to the outer enamel surface, and the current short-circuited through the tooth structure in any desired direction. Decomposition of the pyrozone follows at once the completion of the circuit, and bleaching rapidly ensues. By applying the negative electrode to the enamel surface the bleaching effect is produced immediately under the point of contact, and can thus be brought to bear on any area of local discoloration at will. The treatment of pulpless teeth in the manner indicated, says the writer, is an advance over former methods, and one of more significance than may appear from a casual observation.

Bleaching a tooth by any method which insures thoroughness of the operation is equivalent to absolute sterilization. This, no doubt, is attainable with pyrozone unassisted if sufficient time is taken to accomplish the result; but by means of the cataphoric action of the electric current as noted, pyrozone is driven to the ultimate ramifications of the tubuli, and its active oxygen set free by the current in direct contact with any organic debris which may be present as a menace to the future comfort and integrity of the tooth.

It is evident, says the writer, that the cataphoric method is applicable to the therapy of pulpless teeth by other medications than pyrozone, and a wide field of possible usefulness in this department will, no doubt, be opened up by further investigation. The writer says he has tested the cataphoric application of twenty-five-per-cent. pyrozone in the bleaching of teeth with most satisfactory results, which in point of rapidity and efficacy were, beyond all question, superior to that resulting from applications of the same material when used without the aid of the electric current.

REPORT OF
SEVEN CASES OF DOUBLE CASTRATION
FOR RELIEF OF ENLARGED PROSTATE GLAND.*

BY H. O. WALKER, M.D.,
DETROIT, Mich.

The operation of removing both testicles for the relief of symptoms consequent to an hypertrophied prostate gland is in its infancy, and is therefore claiming the critical attention of surgeons generally. Yet before it becomes an accepted or rejected procedure we must have cumulative evidence as to results, and this is my apology for offering a report of seven cases of double castration that have not heretofore been published.

Case I.—G. B., aged sixty-five years, came into my care January 21st, by advice of his physician, Dr. Campbell, of Lansing, Mich., with a history of enlarged prostate dating back over a period of nearly eight years. Has had to use a catheter for over a year past and has all the symptoms of an aggravated cystitis which I verified by vesical and rectal examinations, together with a urinary analysis. He had lost flesh in considerable quantity, and the night before I saw him had slept but little on account of the frequent desire to urinate, and, as he expressed himself, was ready to submit to any operation however hazardous. Even death was preferable to his present condition. He readily assented to the removal of his testicles, which I did January 23, 1895, and, with the exception of a small hematocele, there were no untoward symptoms and he was able to be about in eight days. On the third day he could retain his urine for from three to five hours. On the eighth day the use of the catheter was discarded and the urine, nearly clear in character, was retained from six to nine hours. He left for his home on the twenty-first day following the operation, when I examined per rectum the prostate and found an appreciable diminution in its size. I received a letter from him two weeks ago in which he was not cognizant of having any difficulty whatever in passing his urine.

Case II.—P. B., aged seventy-one years, has had increasing difficulty in voiding urine for nearly fifteen years. Uses a catheter and desires to urinate at intervals of from five minutes to an hour and a half. Examination revealed a very much enlarged prostate with a centric median bar holding it back from two to three ounces of residual urine with the usual cystitis symptoms. I removed both testicles February 6, 1895. Improvement was appreciable within a week, holding the urine at one time nine hours and a half. Since getting up, however, the improvement has not been so marked, and at times he has had to use a catheter. Yet the cystitis has nearly disappeared, as found by examining the urine a few days ago, and there is a manifest relief in his condition.

Case III.—A man, aged sixty-three years, has a history of prostatic enlargement of seven years' duration. Four years ago I removed from him by perineal section a median pedunculated growth of considerable size which was followed by a fair amount of relief for nearly three years, when the old symptoms gradually returned to their former intensity with an almost constant reminder that he had to void his urine. After several consulta-

tions with me he decided to have double castration done, which I did February 26, 1895. He left for his home two weeks after the operation with a decided abatement of his bladder symptoms. A letter from him, dated March 29, 1895, states that: "There is but little pain in the urine, entire subsidence of pain, urinates but about once in four hours, and does not have to use a catheter."

The cases just reported, although in one there is apparent cure and in the others evident improvement, are of such recent date that I should hardly feel warranted in offering dogmatic conclusions as to permanent results. I have, however, older and more reliable testimony as to the efficacy of this operation furnished by my old friend Dr. Horace Tupper, of Bay City, Mich., who writes me as follows:

MY DEAR DOCTOR: According to promise I made you while here, I have been looking up notes of the history of cases in which I did double castration, and here briefly transmit them to you:

Case I. I was in a French Canadian, aged fifty-six years, who consulted me in 1877 for an enlarged and painful right testicle. Also frequent and painful micturition, necessitating the use of a catheter almost daily, and at times much oftener. I found by examination that he also had a very large prostate as well as the absence of the left testicle, which he informed me had been removed more than a year previous for supposed malignancy. Its removal had improved his micturition materially for several months, but the previous symptoms gradually returned with greater intensity than before, when he decided to have the other removed, which I did, although no cancer cells were found. By the time the wound had healed all the older symptoms had disappeared. I saw him some years afterward, when he said he had had no further trouble with micturition.

Case II. M. C., aged fifty-nine years, called on me in 1882 suffering from painful testicles and persistent desire to urinate of several years' standing. I found a greatly enlarged prostate. He had used a catheter for a considerable period, and had had the bladder aspirated for retention. His principal reason for visiting me was for the purpose of having his testicles removed, as he had been advised by several physicians to have the operation done, since all other efforts to relieve the neuralgia of the testicles had been futile. On the second day after castration he was surprised to find that he could make water without his catheter, and in about two weeks there was but little bladder irritation remaining. Six months afterward he informed me that he could urinate as well as he ever did, and to my surprise he stated that he could enjoy intercourse more satisfactorily than he had for six years past, and, to use his own language, said: "I am sorry that I did not have the damned stones out before."

Case III. B., aged fifty-eight years, consulted me in 1886 concerning the advisability of having his testicles removed for persistent and exquisite pain in them of ten years' duration. He also gave a history of irritable bladder and a frequent use of the catheter. I found, on examination, both testicles enlarged and exquisitely sensitive, and a very large prostate. As it was the opinion of a number of physicians that castration should be done, I accordingly did the operation. He made a good recovery, entire relief from pain and freedom from all bladder trouble in three weeks following the operation. He left the city shortly afterward and I have not seen him since.

Case IV. was that of an old man that came to my knowledge through a consultation with the late Dr. Thomas, of Bay City,
over ten years ago. The fellow was an inmate of the County House, confined there principally for exposing his person on improper occasions. Dr. Thomas was treating him at the time, not only for his mental condition, but for the distressing bladder irritation due to an enlarged prostate gland. He was afterward removed to his home, when another physician assumed charge of the case, and removed both testicles with a view of relieving his mania. The castration cured both the brain and bladder troubles. I have seen him frequently since, and he is perfectly well.

Dr. Tupper's report is valuable evidence in relation to the operation of double castration. The operations were not done with a view of relieving the urinary symptoms, but were evidently done in the first three cases for the purpose of relieving the neuralgia of the testicles, in the last one for the correction of the mental difficulty.

It is not my purpose at the present time to burden you with an account of the development, anatomy, function, pathology, and surgery of the prostate. That is familiar to you all. Suffice it to say that the majority of enlarged prostates, when necessary, can be cared for by proper aseptic catheterism, for I firmly believe that "dirty old catheters" have been the source of the great majority of the cases of cystitis that we meet with in connection with hypertrophied prostates than from any other cause. Aseptic catheterism is much better than antiseptic irrigation.

Operative procedures for the relief of distressing symptoms accompanying hypertrophied prostate are not always attended with any great "haven of rest," except wherein death follows in the wake of the operation. Prostatectomies are questionable in their results. Suprapubic or perineal drainage are simply palliative measures, the best of which is perineal, and do not materially diminish the size of the prostate, the great impediment to urinination.

Sir Henry Thompson aptly describes the condition of the patient after making a suprapubic section: "Now mark his condition. He was able to walk three or four miles a day, was free from pain, and his general health was on the whole good. But he had constantly to wear his silver canula, and supplemented his own faulty anatomy with the ordinary urinary worn by persons requiring such a convenience. Instead of the simple method of relief which normally precedes sleep, this man had to wash out a large part of his urinary tract. First, he removed and washed his canula, then, I suppose, he cleaned out his rubber bag, and, lastly, the relics of his bladder."

The restoration of the normal function of micturition has only been realized to a limited extent by the various operations done upon the prostate. We are therefore in a position to welcome any operation that promises a safer and more radical cure. The reports of castration so far are certainly promising. It unquestionably gives rest to the genital function of the prostate, lessens its size, first, by arrest of inflammation and edema, and afterward gradual atrophy, as has been proved by castration of many of the lower animals. Indiscriminate emasculation will do much toward bringing this operation into disrepute. Simplicity of execution and limited danger will be a great temptation to the neophyte to do this operation. I fully agree with Dr. Belfield in his warnings against castration.

Yet I am willing to trust to the experience of genito-urinary surgeons to make out a diagnosis of the many conditions which may occur in connection with an hypertrophied prostate, and the "mistaken diagnosis" is no more likely to take place than it would with any of the operations upon the prostate. Time, however, and experience of operators will, at all events, settle the merits of double castration for the relief of the hypertrophy of the prostate gland.

27 East Adams Avenue.

A METHOD FOR RESUSCITATION FROM ELECTRIC SHOCK.

BY P. J. GIBBONS, M.A., M.D., SYRACUSE, N. Y.

When a person receives an electric shock sufficient to produce suspended animation, the breathing and heart's action cease; the eyelids are generally half closed, the pupils dilated; the tongue approaches to the under edge of the lips; finally, coldness and pallor of the surface increase.

When one in whom the vital spark may possibly not yet have fled is found, two objects should be aimed at, viz.: first, to restore breathing; and second, to promote warmth and circulation.

When an electric-shocked person is found, he must be treated on the spot in the open air. On no account waste precious time by removing him to a house, unless the weather is intensely cold. Secure a return of breathing, first protecting him, if necessary, from the severe cold by coats, blankets, etc. Keep bystanders off fifteen or twenty feet, place him on his back, loosen all tight clothing, remove false teeth and foreign bodies from the mouth and nose. To excite breathing, resort to Sylvester's method, or any of the well-known methods for resuscitation from drowning, remembering there is no water to be expelled. If no success follows, imitate breathing by inserting the distal end of the tube of my apparatus into the nostrils or the mouth, preferably the nostrils, as in this way the air, during inspiration and expiration, comes in contact with the lining membrane of the nasal chambers. In doing so it allows the membrane to carry out its normal physiological action, and by this means we get so much nearer a normal respiration. The air thus breathed is both warmed and saturated to a certain extent with watery vapor, and much of the dust and other foreign matter floating in the air is removed by adhering to the moist mucous membrane. Or, instead of inserting the distal end, as mentioned above, my face-mask attachment may be used. The nostrils should be excited with snuff, hartshorn, or smelling salts. This can be readily done without the removal of the tube, by allowing the exciting agent to enter the bellows with the fresh air or oxygen.

To Restore Circulation.—The above measures are directed wholly to restoring the breath. This is the first necessity. There should be no rubbing of the surface while this is going on. Should the inclemency of the weather demand the removal of the patient indoors, the above
movements must be kept up even while he is being removed, and on no account should he be taken into a warm or crowded room. When the patient begins to breathe, commence rubbing the limbs. Rub them upward with considerable briskness and pressure. Use silk somewhat warmed; throw a quilt or blanket over the patient, and continue friction under this. The friction in this way will create electricity and heat. Put warm bricks or bottles of warm water at the feet, between the thighs, and under the armpits; but be very careful not to have these things too warm, or much above the temperature of the healthy body.

Physicians may insert the distal end of my apparatus through the mouth into the laryngeal entrance, as they would introduce a tube for intubation of the larynx. Some will probably find it more convenient to perform tracheotomy and insert the tube into the trachea. They can also use electric batteries to keep up body heat, body electricity, and to excite the heart and the lungs to action.

My method, or any other used, should not be discontinued for at least three to six hours, and the operator should not be discouraged if he sees no symptoms of returning life until this amount of time has elapsed. Why no symptoms of life are seen for one or two hours, and

the artificial method again. Sometimes it is necessary to carry on artificial respiration from ten to forty hours after life has been restored. During this time we may test Nature four or five times and find her not able to be self-sustaining; therefore we should keep up the artificial aid until that time arrives when Nature will perform her functions.

My apparatus is a simple double bellows, as shown in Figs. 1 and 2. It is so constructed that when the handle of the bellows is raised the air rushes from the patient's lungs into one apartment of the bellows; simultaneously the other apartment is filled with fresh air through a tube on the reverse side. This air is forced into the lungs by the compression of the handles.

The apparatus is designed to resuscitate persons who have undergone electrical shock, taken poison, been long immersed in water, been subjected to pressure on the center of respiration, or suffered from similar misadventures.

Forced respiration will restore suspended animation more expeditiously and more certainly than any other method now in use. This has been proved by Dr. George E. Fell, of Buffalo, N. Y., and others, during the past ten years.

324 Warren Street.
SOME POINTS IN THE THERAPEUTICS OF
GOUT, THE URIC-ACID DIATHESIS, GRAVEL, ETC.*

BY LANDON B. EDWARDS, M.D.,
PROFESSOR OF PRACTICE OF MEDICINE
IN THE UNIVERSITY COLLEGE OF MEDICINE, RICHMOND;
SECRETARY OF THE MEDICAL SOCIETY OF VIRGINIA, ETC.

It is a common error to speak of gouty conditions as
altogether the heritage from forefathers who belonged to
the nobility. True, the disease was well known, as Lyman
puts it, "among the debauched citizens of imperial Rome,
and it has followed the transfer of luxury and dissipations
from Italian soil to the wealthy capitals of France, Ger-
many, Holland, England, and America." Indeed, we find
it rapidly growing in frequency in our own section where
brains and vim are becoming rewarded by comfortable in-
comes, and where these in turn are inducing sedentary and
plethoric habits and indulgences in the luxuries of the
table, the wine supper, the restaurant, or the club.

But we must not forget that there is the "poor man's
gout." The disease may be acquired by laborers exposed
to cold and damp, who have become accustomed to inordi-
nate potations of heavy beer, taken with half-masticated
luncheons spread over with mustard or other condiments
of the cheap lunch rooms. It is said to be common among
laborers of London employed to raise ballast from the bot-
tom of the Thames who get into the habit of drinking a
gallon or more of porter daily.

By some as yet unexplained pathogenesis, impregnation
of the system with lead—as in plumbers and others—con-
duces to the uric acid diathesis.

Among exciting causes of an attack recognized as
gouty are excesses in eating highly seasoned meats; in
wine drinking—especially champagne; excesses in venery;
body fatigue; exposure to damp cold; prolonged mental
exertions and anxieties. Thus it will be seen that gout is
for the most part a disease that tells of dissipations.
Sometimes, however, no exciting cause is recognizable—
simply the acquired or hereditary predisposition is known.

The diagnostic signs and symptoms of a frank attack
of gout need not detain us; they are classical. Nor need
I describe cases of "irregular," "suppressed," "retroce-
dent," "latent gout," etc.; for that would lead us too far
away from the practical intent of this paper. I may re-
mrk, however, that the manifestations of irregular gout
are extremely diverse in seat and character—sometimes im-
plicating the stomach; sometimes the liver, or the heart,
or lungs, or kidneys, or muscular system, but oftener of all,
the nervous system.

Unquestionably, there is increase or diminution in the
production of uric acid in the system in proportion as
nutrition is perfect or imperfect. Without discussing the
theories advanced in explanation of lithiasis, I indicate the
line of my belief by stating that there are strong reasons
for attributing to the liver the chief part in the formation
of uric acid. So long as this organ can cope with supplies of

* Read before the Richmond Academy of Medicine and Surgery,

der at birth. Such deposits have usually a colloidal covering, as of mucins.

The indications of treatment are plainly to avoid caustic conditions of the urinary tract, use an abundance of milk and free potations of an alkaline water, and there is none better than the Buffalo lithia water of our own State. As the child grows up, he should be encouraged to outdoor exercise short of excess; his diet, in addition to the milk and water just mentioned, should be selected from such articles as fish, chicken, eggs, bread, cereals, fruits, and vegetables. Avoid overeating, especially highly seasoned articles, dark meats, fats, sugar, etc. Special care should be taken as to the adaptation of clothing suited to the weather or season. Flannel in the winter and gauze in the summer are undoubtedly beneficial in all cases where there is even a hereditary or an acquired predisposition to gout. Such clothing hurts no one; it benefits many.

As to radical measures, many of our forefathers learned to be afraid of active treatment in gout. Thus Parry (quoted by Aitken) reports two patients who attempted to cut short an acute fit of gout by plunging their feet into cold water. The relief was instant; but in a few hours both were dead of apoplexy. Sir Francis Burdett reports a similar case; Dr. Wood another; and thus report after report of the same kind might be added. The metastatic lung, heart, or brain symptoms, under such circumstances, all emphasize the presence of uricemia. The urine, loaded with uric acid, may also irritate, or inflame, or even partially obliterate the urinary tubes, and then follows interstitial nephritis, or fatty metamorphosis of the kidneys, which impede the filtering functions of these organs. When such renal lesions as prevent proper elimination exist, we get from some medicines, not the therapeutic effect sought, but the toxic action of the drug employed. Hence the special necessity of great prudence in treating cases of gout, and of frequent painstaking uranalyses, not only for albumin, but also for extractives in the urine.

A great deal has been said in abuse of purgatives in gout, chronic or acute. Granville states that they are harmful "in direct proportion as they promote discharge of the fluids from the intestinal surface and leave the urine concentrated." Yet we must not forget that constipation is often an aggravating complication which demands relief. No agent possesses better effect as a laxative in lithemic conditions than cascara sagrada—just enough of a good fluid extract to move the bowels freely once or twice in the twenty-four or thirty-six hours.

As for remedial agents that have been praised in the treatment of gout, uric-acid diathesis, and gravel, they are too numerous to enumerate. The National Dispensatory indexes over a hundred. Among the vaunted proprietary preparations, Reynolds's specific is said to owe its virtues to the selection of the colchicum used in its manufacture. Tongaline, which has such a long array of professional recommendations, contains the salicylates of sodium, pilocarpine, and colchicine, beside the antineuralgic tongue and extract of cinchona.

Colchicum is an old, well-tried, and faithful remedy if used in keeping with the teachings of experience and ob-

servation. We must not forget that its effect varies according to the idiosyncrasy of the individual. The emetocathartic effects are never required to assuage the pains or to allay the symptoms of "an attack of the gout." Indeed, purging is not desirable, and the vomiting effect is highly objectionable—it is dangerous. It is best to see how small a dose will secure the almost specific effect. Hence never begin with a dose exceeding twenty minims of the wine or tincture two or three times daily; and if twelve or fifteen minims twice a day—morning and night—will suffice, adopt that dose. Tincture of aconite, in one- or two-drop doses, combines well with the colchicum to mitigate the pains of the gouty.

Salicylate of sodium, in fifteen- to twenty-grain doses, in solution, three or four times in twenty-four hours, unquestionably possesses nearly specific virtues in gout, and is even more valuable than colchicum. It both prevents the formation of uric acid in the system and assists greatly in eliminating it when present in excess. It shows its virtues most decidedly during an "attack of gout," whether acute or chronic. It lessens the urgency of many of the most distressing symptoms of uratic deposits, or so-called metastases, especially those referable to the heart or lungs.

During the intervals between attacks much benefit will be derived from five- to eight-grain doses, three times daily, of potassium iodide, especially if there are kidney or vascular complications.

When neurotic troubles persist, as evidence of the presence of uric acid in the system, phosphate of sodium is of undoubted advantage, asHang originally pointed out. It should be administered in solution during the intervals in doses of about a drachm three times daily.

As a tonic for debilitated states, arsenic acts better than iron. Two or three drops of Fowler's solution of potassium arsenite, well diluted, should be administered three times daily.

Nearly specific virtues have long been attributed to lithium preparations. And in the use of lithia waters I have great confidence, especially in dealing with lithemia or uric-acid gravel. Bartholow remarks that "in the so-called uric-acid diathesis, in renal calculi composed of uric acid, and an irritable bladder from an excess of acid in the urine, the salts of lithium are useful. In case of a renal calculus, a very protracted use of a well-diluted solution is necessary."

This brings us to the consideration of alkaline diuretic waters as a treatment of chronic gout, of the uric-acid diathesis, and of gravel. All authorities agree as to the value of large potations of water in order to flush out the lithic-acid compounds from the system through those wonderful emunctories—the kidneys. Singular contrarieties of theoretical therapies are just here shown in certain books. Some acknowledge the virtues of well-diluted solutions of lithium salts, yet advocate the use of pure water. Why not get the benefit of both lithia salts, well diluted, and of a light table water by at once adopting some well-known and well-tested lithia water?

As to the choice of alkaline waters, there are like errors by some of the best text-book writers. Professor Osler,
for instance, in his work on Practice of Medicine, writes: "Waters with the sodium salts should be avoided." And yet in the very sentence before this he says: "Potash water, Apollinaris, or Seltzer water should be taken freely." Every one knows that sodium salts are the chief saline constituents of both Apollinaris and Seltzer waters. There is nothing in clinical evidence to show that such waters should be avoided.

There is a prurience, it would seem, on the part of certain authors to recommend spas and springs of foreign countries. Why this is so I can not imagine. If, therefore, I limit the application of my further remarks to the Buffalo Lithia Springs of our own State, it is because they supply the waters with which all of us are most familiar in the treatment of the conditions under discussion, and because they have passed the ordeal of clinical tests and been found to accomplish the ends in view. That I have abundant authority for this statement, I will show by saying that the lamented Dr. Alfred L. Loomis, not long before his death, stated that "for the past four years" he had used Buffalo lithia water in the treatment of chronic interstitial nephritis occurring in gouty and rheumatic subjects with marked benefit. Dr. George R. Fowler, of Brooklyn, attending surgeon to St. Mary's Hospital, in an article in the Reference Handbook, speaks of the same water as potent in its effects on the digestive and excretory organs; hence as specially indicated in dyspepsia in, or consequent upon, accumulation and deposit of uric acid or its salts in the system. Dr. August Horn, associate professor of diseases of the skin in the Baltimore University, writes that he has used this water with most remarkable results in cases of skin diseases of a rheumatic and gouty diathesis. Professor John V. Shoemaker and Professor Frank Woodbury, both of the Medico-chirurgical College of Philadelphia, in articles in the New York Medical Journal and the Journal of the American Medical Association respectively, have noted most gratifying experiences after the free use of this water in the uric-acid diathesis, in lithic dyspepsias, etc. The late Dr. James L. Cabell and Dr. William B. Towles, both professors in the Medical Department of the University of Virginia, spoke of the relief following its use in lithic conditions as "very decided, no remedy at all comparable to it," etc. Dr. H. C. Wood, professor of therapeutics in the University of Pennsylvania, after its trial in some cases of invertebrate chronic gout, states that it has afforded much satisfaction. The late Professor Harvey L. Byrd, of the Baltimore Medical College, urged that "it is unsurpassed if indeed equaled" in diseases depending upon or originating in the uric-acid diathesis. Dr. Charles B. Narneode, professor of surgery in the University of Michigan, in the International Encyclopaedia of Surgery speaks of it as "one of the best alkaline waters of this country" in the treatment of gouty affections. Dr. Allard Memminger, professor of chemistry in the Medical College of the State of South Carolina, regards it as "the surest and safest and most agreeable way" of removing from the system the pernicious derivative of uric acid. Dr. William A. Hammond, of Washington, Professor Grome M. Hammond, of New York, Professor Alexander B. Mott, of New York, Dr. Robert Battey, of Rome, Ga., and Dr. John Herbert Claiborne, of Petersburg, have all secured excellent results in gouty conditions from its use. It is not necessary to more than refer to the recorded favorable experiences of Professor Hunter McGuire, Professor James B. McCaw, Professor J. S. Wellford, Professor M. L. James, and other members of the Richmond Academy of Medicine and Surgery who have long used it in the treatment of the gouty or lithic conditions.

In view of this array of eminent names of able practitioners who have long used Buffalo lithia water with the utmost satisfaction in the treatment of gout and the allied morbid processes, and with records of successes just as wonderful as any of those stated in the advertising pamphlets of foreign springs and spas, it is strange that many American text-book authors prefer to dazzle the eye of the student with the names of Vichy, Carlsbad, Seltzer, Apollinaris, etc., without even mention of their American peer, so far as the treatment of gout, uric-acid diathesis, or gravel is concerned. I have never heard of a person with gout or any of the related morbid processes—acute or chronic—that was injured by the use of Buffalo lithia water; I do know of many cases in which it has proved beneficial. Can as much be said of all the vaunted foreign alkaline mineral waters?

Can uric acid gravel in the kidneys or bladder be dissolved or sufficiently disintegrated to secure their expulsion? I affirm my own belief that many of them can be so reduced in size, or to sandy consistence, as to allow them to be washed out by the urine. If time permitted I could report cases in my own practice where calculi detritus has been washed out of the bladder apparently as the result of the use of very dilute solutions of lithium, such as are derived from natural lithia water. But there are enough cases on record—some of which are even more conclusive illustrations than any cases that have happened in my practice. Dr. Frank Woodbury has witnessed (Jour. of the Amer. Med. Assoc., April 29, 1893), as the effect of daily drinking four or five glasses of Buffalo lithia water, the removal of gravel or uric-acid deposits. Dr. David G. Smith, of Oakley, Va., has known the free use of this water to be followed by the discharge of calculi matter through the urethra. Dr. W. C. Wile, of Danbury, Conn. (New Eng. Med. Monthly, February, 1890), noted a case in which this water produced a marvelous effect in the quantity of débris that it brought from the bladder. Dr. B. W. Westlind, of Middletown, Pa., passed a number of calculi as the result of its free potation. Dr. E. C. Laird, then of Haw River, N. C., and Dr. Frederick S. Whaley, formerly resident physician at Buffalo Lithia Springs (Med. Med. Jour., Nov. 17, 1888), report the case of ex Governor Holt, who passed some disintegrated uric acid calculus and sand under the use of the water. Dr. G. Halsted Boyland says "the solvent power of the water is unmistakable," and it so changes the diathesis as to prevent re-formation of red lithic acid and white phosphatic stone. Dr. J. D. Eggleston, of Worsman, Va., had a very gratifying experience in his own person of its solvent action of a uric acid vesical calculus. Dr. Albert Goodwin, of Enfauila, Ala. (N. Y. Med. Jour., Oct. 29, 1892),
CLARK: THE SURGICAL INDICATIONS IN TRIGEMINAL NEURALGIA.

The surgical indications in trigeminal neuralgia have within the past few years been slowly but surely developing. There has been a steady drift from the continued use of powerful sedatives, the reckless removal of sound and useful teeth, and the contracting of drug habits. All must give way before the successful results of surgical procedure. The methods and results of surgical interference in trigeminal neuralgia, tic douloureux, or epileptiform neuralgia, where not due to disease of the brain, as reported by the following named surgeons, are as follows:

Dr. Abbe, December, 1888: The second division of the fifth nerve removed as far as the foramen rotundum and Meckel's ganglion broken up.

Dr. Glass, Utica, 1889: Inferior dental divided by incision made inside the mouth.

Dr. Magruder, of Charlotteville, Tenn., 1889: Two cases. Second division of fifth nerve drawn down and cut off. Inferior dental branch divided after trephining ramius of inferior maxilla.

Dr. Wyeth, 1891: Two cases. Second division divided and proximal end of the nerve twisted.

Dr. Lange, 1891 and 1892: Two cases. Second division cut, bony canal broken down, and nerve destroyed.

Dr. Hartley, January, 1892: Intracranial neurectomy. Second and third divisions of the fifth nerve divided outside dura mater after trephining in left temporal region.

Dr. Tiffany, Baltimore, November, 1893: Four cases. Intracranial neurectomy, dividing second and third divisions of the fifth nerve, employing same method as Dr. Hartley.

These several gentlemen indorse these operative procedures, and report in each and every instance rapid recoveries, permanent relief from pain, decided improvement in the patient's general health, and no special permanent interference of function in parts supplied by the divided nerves.

I desire to add one case to the above list:

A man, aged fifty five years, woodswain. Neuralgia of first and second divisions of fifth nerve upon left side. The pain commenced in 1890 with lightning paroxysms fifteen or twenty times daily, lasting from thirty to sixty seconds. Sometimes the pain would cease for six hours. These pains started and continued in the second division of the fifth nerve for three years, afflicting smell and sight upon the left side of the face. After this, the first division became involved and the pain was continuous. Seven teeth in the left upper jaw were removed in 1893, and two months later the remaining four in the lower jaw, with no cessation of the pain, and during this time all the known

* Read before the Medical Society of the State of New York at its eighty-ninth annual meeting.
remedies were used, the patient finally securing his only relief by frequent resorts to half a grain of morphine. His appearance in May, 1894, was a typical picture of pain and despair. The left eyelids congested, swollen, and laryngeal fluid continually dripping from the corner of the eye.

Operation performed in May, 1894, under chloroform anesthesia. Infra-orbital and supra-orbital foramen located, incisions made, and nerves pulled up with an aneurysm needle and severed. The small, round tip of a Paquelin cautery, at nearly white heat, was then pushed upward and backward through the infra-orbital foramen and back half an inch in the canal, destroying the nerve. Patient drove home a couple of hours later and from that day to this has been perfectly free from pain and continues his outdoor work. Wound healed without feature. There is slight anesthesia of the left ala of the nose and over the eyebrow.

Neuralgia of neurasthenics located in different parts of the body can be materially helped by the rubber adhesive plaster—viz., intercostal, by a broad strip applied exactly as to a fractured rib. Ankle and knee joints can be strapped with much moral if not actual effect.

In neuralgia occurring in the end of the limb after amputation, care should be taken to distinguish between the conical stump and a neuritis which can be cured by dissecting out the nerve instead of reamputation, particularly in the lower extremity.

ELECTRICITY IN MEDICINE
FROM A MODERN STANDPOINT.*

By WILLIAM JAMES MORTON, M.D.,
PROFESSOR OF ELECTROTHERAPEUTICS
AND OF THE DEPARTMENTS OF THE MIND AND NERVOUS SYSTEM AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

INTRODUCTORY.

In accepting the invitation of the president of this society to take charge of presenting this discussion before you, as well as to open and take part in it, I welcomed the opportunity as one which would invite your earnest attention.

The Era of Electricity.—There are times in the history of the world—in the history of medicine—when certain subjects are rife; they come upon us in waves and we are swept along in the stream.

Such a period is now with us as regards electricity. We have had the era of steam, of the subdivisions of electricity—telegraphy and telephoning—the era of vaccination, of anesthetics, of antiseptic surgery; we are now well along in the era of bacteriology, and next the era of electricity is forcing itself to attention, not alone in the general affairs of men but also in the practice of medicine.

We physicians can not, if we strive to do so, keep out of its influence.

Electricity has revolutionized chemistry long since—the fundamental laws of chemistry and electricity are but two aspects of one and the same thing; it has revolutionized physics—for light, or the science of optics, and the science of electricity are now regarded as one and the same science; it is now revolutionizing the industries and the habits of mankind.

We do not for a minute think that electricity will revolutionize medicine, and not even the therapeutics of medicine; for medicine is a complex science, built upon many foundations where electricity is not directly involved, and therapeutics seeks aid from every quarter, and electricity is but one of these aids.

But we do think that in this, the electric age, the physician alone of educated men can not remain isolated from the general advance, can not lag behind in this great branch of scientific thought and practice, for it is he who, in the race for the good and the happiness of the human kind, has ever kept in the vanguard of information in the physical sciences even at great sacrifices to his personal comfort and without remuneration.

Does the physician ask for evidences of this electrical era, he has but to look about him.

The wheels of the machine shops are beginning to turn by electric motors; the wheels of the street cars now turn, and ere long the wheels on the great trunk lines will turn by the same motive power. Electricity is supplanting steam.

Our houses and cities are lighted by electricity, and soon our homes will be warmed by the same agency and our cooking done.

Electricity, either by electrolyzing sea water or in the production of ozone, is already the most available and powerful disinfectant and germicide in the world.

It is no wild assumption to say that the health of the closed ranks of our civilization in cities and towns may at no distant date be maintained by electric purification.

To obtain electricity to do these manifold works mighty dynamo machines of five thousand horse power each are already constructed, and, to secure the power to transform into electrical energy, the mountain streams and the waterfalls the country over are being corralled.

Niagara Falls itself has been tapped to yield a hundred
thousand horse power to be conveyed in the shape of electric energy along wires to distant cities.

**Relation of the Physician and the Electrical Engineer.**— How, then, shall the physician keep pace with these strides in such a manner that medical science shall not suffer? Obviously, by but one method, that of informing himself as to the fundamental laws of electricity and their applications in practice.

To do the first, he must study electrophysics, and to study this he must turn to the work of the electrical engineer. The two branches to a certain extent blend.

Already the electrical engineer all over the world is invading the domain of physiology; he is studying the physiological as well as the physical effects of the currents he handles; in fact, are the former not dependent upon the latter? In like manner the physician is turning to the electrical engineer. Here, in this union, is the genesis of modern electrotherapeutics. But here, you say, is new work for the overburdened physician. True, and it can not be helped.

Already medical science is by far too comprehensive for one average man to grasp, and hence its subdivision into specialties. Must eco-therapeutics then be narrowed down to specialists? I reply, its advanced and best work must certainly be in such hands, but there still remain a large number of specific procedures of great importance in medicine and surgery which may be perfectly grasped and aptly applied by the general practitioner. And the number of such procedures will more and more increase as the medical schools of the land adopt or perfect teaching of elementary electrophysics in their curriculum, and as the newly trained men spread outward to their work. But, in conclusion, you ask, is it worth our while to devote attention to electricity in medicine? On the one hand, it is condemned; on the other, exorbitantly praised. Who is right? We have in the first place shown that if the physician does not take up this question he will be hopelessly behindhand in a branch of science which now closely interests the entire civilized world, and there can be no doubt that in not taking it up he may be charged with neglecting the interests of his patients.

Furthermore, he can not decide upon the merits of the uses of electricity in medicine if he is in entire ignorance of the subject. The true position to-day is that of conservatism—a conservatism based upon knowledge of the subject, and not that pseudo-conservatism based upon skepticism; for a blind and unreasoning skepticism has no place in science any more than an equally blind faith.

There can be no doubt that in selected cases, and with skilled use, electricity can render to medical practice important aid, now unavailable by reason of the inadequate attention paid to the subject. This aid I do not urge as a specialist, nor as an “electrician” so called, for I and others engaged in the study of the modern uses of electricity in medicine claim only the title of physician, of physicians who are free to use and do use all other remedies and measures they see fit, and who in using electricity regard it but as one out of many means whereby disease may be palliated or cured and humanity benefited.

To show you that it is worth while to heed the warnings of the times, and to study the use of electricity in medicine, is the guiding motive which has induced me to invite your attention to the subject.

**Electrophysiology.**

Electrophysiology comprises—

1st. The manifestation of electric phenomena by the living organism: animal electricity; electrogensis.

2d. The reaction of the living organism to the electric excitant.

I. Animal Electricity; Electrogensis.—The time will, no doubt, arrive when it will be recognized that the science of biology and that of chemistry and of electricity are so interwoven and interdependent that they must be considered together in order to arrive at any adequate conception of the processes of life. Certain it is that the development of electromotive force and, as a consequence, of currents of electricity has long become a familiar phenomenon of physiological action.

Electrical currents characteristic of the muscles, the nerves, and the glands of uninjured animal tissues are now generally accepted. This view in no sense postulates that “electricity is life,” but merely that electricity, like heat for instance, is both a product and an essential accompaniment of the vital processes. It would serve no practical purpose to here present in extenso the received views relating to these currents of electricity characteristic of living beings, for, beyond the fact of their existence, electrophysiology furnishes us with but little information; their polarity and consequent directions of flow and their causes are not yet established. Animal electric currents were discovered by Galvani, studied by von Humboldt and Matteucci, worked out in detail by Du Bois-Reymond, Engelmann, Hermann, and others, while within recent years Tarchanoff has demonstrated beyond question that in the skin of man an electric current is set up by excitation of organs of special sense or by simple mental activity. Tickling of the skin sets up within a few seconds a cutaneous current, rising rapidly to a maximum, and persisting several minutes after the excitation is over; the parts of the skin having the greatest number of glands are negative to those parts having a less number. The same result is produced by other forms of excitation of the skin, such as the electric, the thermal, or those of pain, or by a bright light falling upon the eye, a loud noise, or a strong odor, also by the mental effort of solving arithmetical problems or by the influence of emotions. The causation of these currents has by some been attributed to chemical activity, by others to changes of form of tissue elements. When the exact manner of their genesis in our bodies shall have become established by the future electrophysiologist it will become of great importance to electrotherapy, for by aid of the ordinary battery current we may be able to annul or enhance the activity of the tissue processes which produce them. In a paper* read before the American Electrotherapeutic Association in 1892, the writer endeavored to solve this latter question.

* Medical Record, September 3, 1892.
and thus to introduce greater accuracy in electrotherapeutic procedures by advancing the two following propositions, based upon a generally accepted conclusion that the chemical processes of metabolism are the source of the currents, and that therefore—

1. Catabolism, or destructive metamorphosis of tissue (comparing the catabolic process to the zinc of a galvanic battery), must inevitably be electropositive, or, what amounts to the same thing, must present the sign of negativity.

2. That admitting this to be true, every focus or area of tissue undergoing katabolic or destructive chemical changes may have applied to it by an external galvanic battery—
   a. The positive pole, which will augment the destructive or catabolic exchanges.
   b. The negative pole, which will annul the destructive or catabolic exchanges.

If these propositions are sustained in practice we have, in certain cases, but to determine the electric sign of a certain given diseased part to be able to apply to that part that pole of the galvanic battery which shall either retard or hasten the chemical tissue changes underlying and constituting the morbid process. I have tested many instances of catabolism and found them to present the negative sign, and therefore to be, as I have maintained, electropositive in their nature, and am now collecting the data to demonstrate the second part of the theory—namely, that this fact may be of use as a therapeutic guide in the administration of electricity. As to the first part of the theory propounded, that catabolism or the destructive processes of life present the sign of negativity, I am glad to find that it has been adopted by Biedermann in a paper read last year, based upon investigations into the nature of the electrical currents developed by the glands of the body.

"Biedermann points out that in the gland cell we have a structure pre-eminently liable to variations from the balance between constructive and destructive events. That part of the protoplasm of the cell engaged in the elaboration of the secretory products, though ordinarily the seat of an excess of catabolic over anabolic activity, must at the same time be in a highly unstable state, and liable under certain conditions to an overthrow of balance to the opposite side. The electrical sign of a part in which catabolism is in excess of anabolism is negative as contrasted with that of a balanced part; more negative still to a part where anabolism is in excess of catabolism, and of course vice versa as regards positivity. Thus, it is supposed, differences of potential may be originated in the cell as the result of its vital processes, and the cell current will depend, as regards its direction, upon the predominance of either one or the other processes, and the relation of the resultant condition to that of the rest of the protoplasm. The act of production of the secretion by the cell is one in which catabolic action is in the ascendant, so that part of the cell in which the secretion is occurring should be negative.

tive to the deeper parts with a resultant ingoing current when put in circuit; and upon this hypothesis Biedermann explains the ingoing 'current of rest' as being the electrical expression of a continuous and predominantly katabolic activity."

In a recent number of Science Progress Mr. E. Waymouth Reid reviews the various theories of animal currents, and is inclined to accept what he terms the Biedermann theory, unaware, doubtless, that this very theory had been published by the writer and very exhaustively worked out in the article alluded to, published in the Medical Record, September 3, 1892, entitled A Possible Electric Polarity of Metabolism, and its Relations to Electrotherapeutics and Electrophysiology. It is certain that when more definite knowledge of animal currents is afforded by electrophysiology electrotherapeutics will advance equally and by positive steps.

II. The Reaction of the Living Organism to the Electric Excitant.—Of all excitants to living tissue, there is none to which it is more susceptible, compatible with the preservation of its structural integrity, than to the electric.

There is, furthermore, no known excitant which may safely permeate to every recess of tissue as electricity will by known physical laws of current conduction.

From both points of view electricity is therefore qualified to excite, independent of volition, the irritability of all tissues.

The far-reaching effects of these statements are realized when we recall that fully nine tenths of the soft parts of the body are composed of contractile tissue.

The time at my disposal permits of but the briefest allusion to the physiological reactions.

They may be classed, some of them doubtless overlapping, as—

1. Protoplasmic reaction.
   1a. Nerve reaction.
   1b. Motor...Muscular contraction.
   1c. Vaso-motor...Circulatory changes.
   1d. Trophic...Nutritional changes.
   1e. Reflex...Reflex action.

1. Protoplasmic Reaction.—Movements of protoplasm, both vegetable and animal, are caused by the electric stimulus.

In unicellular organisms, like the Amoeba diffluens and the Arcella vulgatia, the spherical shape is assumed; as regards the vibratory cellia, a change occurs both in the frequency and in the amplitude of the vibrations.

In the human body the irritability and contraction of protoplasm and its modifications afford the basis of familiar nerve and muscle reactions, as well as an available explanation of other reactions still novel and unexplored.

When the protoplasm is at peace the organism is at peace, and the feeling of health is the result.

2. Nerve Reaction.—That nerve and muscle tissue are stimulated by variations in current strength is the most familiar fact of electrophysiology. To trace out the modifica-
tions of function of a living organism caused by stimulating and setting into increased activity the sensory, motor, vasomotor, reflex, and trophic nerves would lead us over an extensive department of physiology, for, in the case of the sensory nerves, the great centers—cortex, basal, and spinal ganglia—have their nutrition, function, and even their structure altered by ingoing impressions from the periphery (Hodge); in the case of the motor nerves, both the great mass of the skeletal muscles, as well as organs and tissue provided with even the least muscular fiber, are caused to contract with corresponding tissue and circulatory changes; in the case of the vaso-motor nerves, circulatory and nutritional results are brought about; and, finally, in the case of the trophic nerves, ending in the tissues where nutrition solely is concerned, modern research has demonstrated that a profound increase in metabolism is established.

I would not be understood to say that every perfunctory or ignorant administration of electricity will accomplish all of these results, but rather that in the hands of one fairly well informed such results may be obtained. The merest tyro may secure the muscular contraction effects, but many of the others require skill, knowledge, and, in some instances, machinery, for the production of forms of electricity not generally available.

**Specific Action of Electricity on Nerves and Muscles.**—A galvanic, faradic, or franklinic excitation of a motor nerve removed from the body, yet left in connection with its muscle, causes an energetic contraction of the muscles.

The excitation may be direct or indirect; it is direct when applied to the muscle itself; indirect, when applied to the nerve. The excitation may be by the bipolar or the unipolar method; when bipolar, both electrodes act upon the nerve or muscle; when unipolar, one electrode—the active one—is applied to the nerve or muscle, while the other electrode—the indifferent one—is applied at some remote situation. These methods apply also to actual practice. The excitation produced indirectly (on the nerve) produces the strongest contraction; all the muscular fibers connected with the nerve respond. A powerful current is required to produce a contraction (direct) of muscular fiber irrespective of its nerve supply.

**Physiological Tetanus and Single Contraction.**—These are the two possible modes of muscular contraction.

Each requires that a variation of electromotive force be employed. For the single contraction, a single electric impulse, like the "make" or the "break" of the galvanic current, or the single impulse from an induction coil or a spark, will suffice; for tetanus, a succession of electrical impulses, usually secured by the use of the induction coil, is required.

Up to about twenty electrical impulses a second, only a single contraction of a muscle occurs; beyond that number the muscle fails to relax, and tetanus ensues.

The rate of the number of impulses a second is termed the "frequency" of the current.

D'Arsonval has shown that at a frequency of twenty-five hundred impulses a second a maximum strength of contraction is reached which is sustained up to five thousand a

second, and diminishes from that point onward to ten thousand a second, when no contraction effect whatever is produced. But, though the motor (or sensory) nerves are not affected at these high rates, the trophic nerves are, as will be shown later on. A constant or galvanic current passing through a muscle produces no contraction, nor is contraction evoked by the same current traversing the motor nerve.

**Electrotonus.**—Though no muscular contraction is called forth by the passage of a constant current through a nerve or muscle, nevertheless it is otherwise modified, for its irritability is altered; that part of the nerve submitted to the influence of the positive pole has its irritability diminished; that submitted to the negative pole has it augmented.

The former—anodal diminution of irritability—is termed an electrotonus; the latter—cathodal exaltation of irritability—is termed catelectrotonus.

A practical point seldom noted is that, if the galvanic current producing these effects be interrupted, the states of irritability referred to are reversed—namely, the anodal region exhibits exaltation, and the cathodal diminution irritability.

These principles are applied in practice.

**The Law of the Order of Contractions.**—This law, called Pfliiger's law, expresses the facts relative to the respective powers of a positive or a negative pole and of an opening or a closing of the circuit to cause contractions of muscles.

The main feature of the law is that at the closure of a constant current the strongest contraction takes place at the cathode or negative pole, and at the opening of the circuit the strongest contraction takes place at the anode or positive pole.

Expressed in symbols, where C stands for cathode, closure, and contraction, A for anode, and O for opening, we may write the sequence in terms of relative strength as follows:

\[ C \ddot{C}C > A \ddot{C}C > A \ddot{O}C > CO \ddot{C}, \]

a formula which I often recall by aid of a mnemonic—viz., C A A C giving the first letters and adding CO, making C A A C O, to decide upon the order of the cathode and anode in the second and third members.

It should, however, be noted that galvanic alternatives will give stronger contractions than any other proceeding of opening and closing the circuit. This law finds its most important bearing as regards the reaction of degeneration of Erb where, in the degenerating muscle, upon closure the anode causes a stronger contraction than the cathode, an evident reversal of the normal formula given.

**Effects upon Metabolism: Nutritional Effects.**—To excite a nerve, to cause muscles to contract, to produce sedation of nerves (anelectrotonus), or sedation of muscular excitability, comprises a large portion of the physiological effects usually expected of percutaneous electrical applications; but there remains a further effect of a certain class of electrical currents far surpassing in importance any of those named.

We refer to the decisive effect upon the metabolism of
the organism set up by high frequency, high potential currents, emphasized by D'Arsonval by a series of decisive laboratory experiments.

In 1881 the writer devised a mechanism consisting of a Holtz or influence machine and Leyden jars, by means of which a new order of current was established—namely, condenser currents in rapid discharge—and termed his current the static induced current. This current was not a single condenser discharge, but a regulated series of such discharges.

At that time, and later on in a publication in 1891—both publications prior to any other describing a current of this nature—he called attention to the peculiar physiological effects produced by his current.

In 1892 and subsequently, Nicola Tesla, by aid of this same mechanism and instruments of far greater power and precision, developed the wonderful physical effects which are now known as the "Tesla effects."

Professor Elihu Thompson also took part in this development, and Professor D'Arsonval, of Paris, addressed himself assiduously and brilliantly to the development of the physiological effects.

Thus sprang up the high frequency, high potential current of these days. The static machine as a feeder to the Leyden jars has for the production of the physical effects been replaced by specially constructed dynamo machines or induction coils, and the static induced current has been transformed by "step-up" or "step-down" transformers; but its principle still remains the same; it is essentially and always a condenser current, produced by a stream of sparks from discharging condensers from whose external armatures is taken a current characterized by its extraordinary high electromotive force and by its oscillatory or alternating nature.

The physiological effects of this current, the static induced current, when human beings are submitted to its influence, are remarkable.

As we have seen, alternations beyond ten thousand per second produce no contraction effect upon nerve or muscle.

The high frequency currents here referred to run easily up to say one hundred thousand alternations per second and a voltage of one hundred thousand, and produce no effect upon motor or sensory nerves: no appreciable sensations are produced and yet there is a profound effect upon nutrition: the elimination of urea, of carbonic acid, and of water is increased from forty to fifty per cent, while, correspondingly, the uric acid and other incomplete products of tissue combustion are diminished.

In short, the consumption of oxygen is increased, and the sum total of the complete end products of vital functions is increased at the same time that the incomplete products of combustion are diminished. That a powerful current is traversing the body is shown by placing an electric lamp in circuit with the patient's body and noting that it lights up though no sensations of the passing current are felt.

The watts, or horse power, or total electric energy required to light such a lamp would, if it traversed the body at lower rates of alternation, cause death.

Why it is that currents of such enormous voltage and frequency are harmless to the subject submitted to their action is as yet unknown. Various explanations have been offered; among these the most plausible is that there is actually no horse power in such currents; but, on the other hand, if this be so, why is it that the lamps held in the hands and in circuit with the body are rendered inconsiderable, for the current sufficient to produce this incandescence would, as has been said, ordinarily prove fatal?

This problem remains to be solved.

The practical point to which I would here call your attention is that the static or influence machine, in all of its manifestations as used in treatment—spark, spray, douche, and static induced—is essentially a high-frequency, high-potential current, and it is a source of gratification to the writer, who in 1880 introduced the practice of using these machines into this country, and who has long advocated their efficiency in medical practice, to find that his faith was well founded, though the scientific explanations were not at that time discovered and enunciated, and are indeed not yet fully furnished us.

It is evident that currents of this nature have a great future before them in all diseases characterized by incomplete combustion processes and malnutrition, like, for instance, rheumatism, gout, anemia, and chlorosis, neurasthenia, melancholia, etc.

To take a single concrete instance, who would not prefer to cure a case of rheumatism by curtailing and rendering impossible the formation of uric acid by carrying its oxidation on to urea, rather than to render the uric acid soluble by present means while not in any wise diminishing its production?

In such directions as these, gentlemen, electrophysiology and electrotherapeutics are tending.

(To be concluded.)

GLUCOSE AND CANE SUGAR AS FOODS.*

By E. H. Bartley, M.D.,
Professor of Chemistry and Toxicology in the Long Island College Hospital.

Glucose, either in the pure state, as invert sugar, or mixed with cane sugar, is a daily article of diet. It is an important question to determine whether there is a difference in the effects of this sugar and cane sugar. Since glucose has become a cheap commercial article, it has found numerous uses in the arts and as an article of diet. Several foreign chemists, notably Nessler, Schmitz, and Landbeck, have professed to have found in commercial glucose an unfermentable substance having injurious effects.

The experiment has been tried of adding glucose to grape juice before fermenting, to fortify the wine to be produced. This was a failure because of the disagreeable after-effects from drinking the wine.

A few years ago enormous quantities were used in the manufacture of beers. Several expert brewers have in-
formed the writer that such beers always have a bad after-effect. In 1882 a committee of American chemists examined the question with great care, and reported that there was no evidence before the committee that maize or starch sugar (glucose), either in its normal condition or fermented, has any deleterious effect upon the system, even if taken in large quantities. While the ability and standing of these chemists cannot be questioned, we may ask what experiments were made by them as to the effects of the long-continued use of glucose. In discussing the effects of an article of diet that is to be used by all the individuals of a community, the sanitarian is obliged to observe the effect upon all classes. Investigating committees are apt to select only healthy subjects for such observations, which may lead to conclusions not consistent with the truth when all classes are considered.

The physician or the sanitary authority is bound to protect the weak and diseased, as well as the robust and sound. This point is frequently overlooked. The real question should be, Are there any considerable number of persons seriously affected by this article of food, and who should be warned against its free use?

Commercial glucose is a mixture of dextrose, maltose, dextrin, and traces of other substances, in varying proportions in different samples. The chief ingredient is dextrose (grape sugar or diabetic sugar). This sugar is not furnished in large quantities by many natural sources of food, and is prepared in the human body only in the intestine from cane sugar taken with food or during the act of absorption of this sugar or the maltose formed by the digestive ferments upon starch. In other words, it is prepared by the intestinal mucous membrane in the act of removing the maltose and cane sugar from the digestive tube. Except in a few substances, like honey, raisins, and figs, vegetable foods contain very small quantities of dextrose. The principal forms in which sugar is presented to the stomach by Nature’s foods are either milk sugar or cane sugar. These sugars are very different in properties from dextrose, and require digestion before they can be used in the body. They are not capable of assimilation as such, and must be converted into a glucose before they can be used, and this is only done in the intestine. From this it would seem that it was not intended that dextrose and levulose should be taken in any considerable amount in our food. They are not natural but artificial foods.

Commercial glucose as prepared by the action of sulphuric acid upon starch is not a physiological product, and is different from that produced by the digestive process. Glucose checks the action of the diastase of the saliva as well as the pepsin of the gastric juice. The same can be said of cane sugar in a less degree. Glucose undergoes both the lactic and alcoholic fermentations with great readiness and leads to gastric disturbances, besides the above-mentioned effect in causing salivary indigestion.

These effects are more marked in persons who are subjects of gastric or gastro-duodenal catarrh. Catarrhal mucus seems to cause the glucose to undergo this change with astonishing rapidity. The lactic-acid hyperacidity increases the irritation of the mucous membrane and thus aggravates the gastric catarrh. The excessive and continual use of cane sugar will often cause the same phenomena, but not so readily. The effects of a continual use of large quantities of sugars, especially of glucose or invert sugar, and to a less degree cane sugar, are general malaise, defective nutrition, anemia, salivary and gastric indigestion, and gastric catarrh. These effects for some reason have appeared to me to be more common in the young and in girls than in adults and boys, probably because of the greater indulgence of the former.

Glucose is taken in the form of candies, in the form of invert sugar—a mixture of dextrose and levulose—in cooked acid fruits, jellies, preserves, and some forms of cake and pies. It is a well-known fact that cane sugar is inverted by heating it in presence of acids. This change takes place when sweetened fruits are cooked. Every physician meets persons who can eat raw apples without stint and without after-distress, while they can not eat apple sauce or apple pie without distressing after-effects. These same persons can drink lemon juice and water, but are sickened by lemonade or lemon pie. It is not a rare thing to find persons who can eat rock candy or maple sugar with no unpleasant after-effects, but the same amount of ordinary glucose candy will cause distress or produce what is usually known as “bilious vomiting.”

The writer has known several cases of death produced in this way, and in every case it was with candy containing glucose. He has never seen a case of serious illness from eating pure cane-sugar candy, although such cases might possibly occur. Attacks of acute gastric catarrh, or acute indigestion with fever and vomiting, are more commonly met with as the result of over-indulgence in sweets.

The writer has notes of at least two cases of recurring choren, one in a girl and the other in a boy, which recovered almost without medication by restricting the diet to articles containing no sugar. The boy had the disease for two years in spite of medication, and recovered by restricted diet and the use of peeps and hydrochloric acid, with laxatives.

A young lady who represented that she had vomited three times a day for a year, and who had almost lived on home-made cake, recovered on a restricted diet and a mineral acid after meals. The vomiting returned whenever she ate cake, and ceased when all cooked sugar was withheld, and without medication of any kind.

This young lady illustrated in a marked degree a remote effect of the sugary diet which is often seen—viz., a catarrhal inflammation of the genito-urinary organs and of the throat. I have attributed this remote effect to the uric acid produced by the disturbances of nutrition. In the throat it may be due to an extension upward of the catarrh of the stomach produced by the excessive use of these sugars. The author can produce in himself a severe headache, preceded by marked malaise, at any time by eating apple sauce cooked with sugar, while he can eat raw apples without any such effect. He can eat currants or any of the small fruits with sugar, with no effect; while the same fruits, when cooked with sugar, produce the headache, etc. Commercial glucose produces the same effect. He has
never found sugar in his urine. I can conceive of no explanation of these phenomena, except that it is the invert sugar that produces the trouble.

I have so often made the experiment and have so often seen the same result, both in myself and in others, that I am convinced of the difference in effect between raw cane sugar and cane sugar cooked with acid fruits.

Hydrochloric or phosphoric acid seems to materially lessen these effects, probably by checking fermentation in the stomach.

The following facts may, in part at least, explain why we might expect that dextrose or invert sugar would disturb the digestion and nutrition more than cane sugar or milk sugar:

1. The greater case with which both dextrose and levulose ferment. Dextrose and levulose undergo lactic fermentation in presence of catarrhal mucus with extreme rapidity.

2. The retarding effect of invert sugar upon salivary and peptic digestion seems to be more marked than that of cane sugar, maltose, or lactose. Salivary indigestion may be produced in this way from an excess of invert sugar or of cane sugar. Epigastric heaviness is often marked in sensitive subjects after sweet desserts, but not when these are omitted.

When cane sugar or starch is taken into a previously washed stomach, only traces of lactic acid can be found in the contents of the stomach in an hour (Ewald). The sense of heaviness in the epigastrium seems to me to be due to the retarding effect of the sugars on stomach digestion, and the liquefying action of the saliva on the starchy foods.

3. The more ready absorption of the glucoses—four times that of peptone—is a third reason why they should not enter largely into our foods. When commercial glucose, or invert sugar, is taken as food, its absorption begins in the stomach and continues until it is all absorbed. This rapid pouring of dextrose into the portal blood may prove too great a tax upon the liver, and a portion of it pass this organ. Functional disturbance of this organ will be the result. The blood may be overcharged with dextrose, and a little of it find its way into the urine.

This, however, is a less serious accident than the tax it entails upon the oxidizing power of the blood. The blood is able to carry only a definite amount of oxygen, and if it is flooded with too much easily oxidizable material, this appropriates the oxygen that ought to be used to oxidize the waste products from the physiological action of tissue cells. These waste products must, in such circumstances, either be excreted in a half-oxidized state or accumulate in the blood. An excess of uric acid is certainly produced, with a highly acid urine and an artificial uric-acid dyscrasia, with all the symptoms of this condition.

A common and rational symptom of the deficient oxidation in the tissues is the marked feeling of malaise which such persons suffer, and which is common in diabetics. That this malaise is due to this cause is evident from the marked improvement when sugar in all forms is withheld from the diet.

When a condition such as I have described has once been established, cane sugar, maltose, lactose, and even starch often seem to aggravate the symptoms. Either from the action of the gastric mucus or the fermentations lodged in the membrane, the fermentative changes in the digestive canal are produced almost as readily by cooked starch as by the sugars. It is certain that catarrhal mucus can partially invert cane sugar. For this reason, little difference can often be seen between the action of cane sugar and invert sugar in subjects of gastric catarrh; but in the production of this condition there seems to be a marked difference.

I have attributed the injurious action of invert sugar to the dextrose rather than the levulose, because the latter is so much more readily assimilated than the former, and does not ferment so readily.

It is also uncertain whether levulose is absorbed as such, or is converted into dextrose during absorption. We do know, however, that levulose can be eaten in considerable amount by diabetics without increasing the sugar in the urine.

We may summarize the differences in the action of cane sugar and dextrose (or invert sugar) when taken as food as follows:

1. The former is a natural food while the latter is exceptionally so.

2. The latter undergoes lactic fermentation much more readily in the stomach and duodenum than the former, and interferes more with salivary and gastric digestion.

3. The latter is more rapidly absorbed than the former, owing to the gradual formation of dextrose from the latter during absorption. This rapid absorption may overtax the liver and oxidizing process in the tissues, preventing the proper destruction of waste products of cell action.

4. Clinical observations coincide with these deductions.

The only doubt to be raised in this respect is as to how far the author has been able to separate the effects of the overeating of cane sugar from those believed to be due to invert sugar or dextrose. The observations began long before the reasons for the difference in the action of the sugars was known to the observer. These reasons are brought out here to explain the clinical phenomena.

THE PREPARATION OF ASEP'TIC CATGUT BY MEANS OF FORMALIN.*

By R. H. CUNNINGHAM, M.D.

(From the Physiological Department of Columbia College, New York.)

While engaged upon certain experiments necessitating the use of fairly slowly absorbable sutures, I determined to try the effect of hardening catgut in the now well-known histological hardening reagent, formalin, and the results from this procedure are so interesting to myself that a brief report of them will prove, I hope, equally interesting to others who may not have tried it already and who may desire to use sutures or ligatures prepared according to the method described below.

Since the discovery of Berlioz and Trillat in 1890 that

* Read by invitation before the Section in General Surgery of the New York Academy of Medicine, April 8, 1899.
a solution of formalin of 1 to 5,000 parts was capable of preventing the growth of micro-organisms in meat juice, a number of writers (Hanzer, Aronson, Lehman, Gegner, and others) have satisfactorily demonstrated its great potency as a germicide. Its employment in very dilute solutions for sterilizing instruments and the hands has been advised by several investigators, but it should be used in very diluted form, for if a concentrated solution is applied to the skin a peculiar necrosis occurs that is unaccompanied by the usual signs of inflammation.*

More to the object of this paper, however, is the property that formalin possesses of uniting with gelatin and with albumin to form insoluble compounds. Thus if a film of gelatin, such as one gets on a photographic gelatin dry plate, is immersed in a solution of formalin for some hours, it is impossible to dissolve the now changed film, even with prolonged boiling in water.

If commercial surgical catgut is wound not too tightly on a glass spool and soaked for two days in a mixture of absolute alcohol and ether (equal parts of each) to thoroughly remove the grease, then rinsed in alcohol for a few moments, † and from this removed to a small jar that has a tightly fitting cover and which contains enough of a mixture of equal parts of formalin and alcohol to well submerge the catgut, after several days the catgut may be removed and the formalin washed out by soaking it several times in fresh alcohol, or, what I consider more preferable, it may be transferred to normal saline solution and boiled for half an hour or more and then be transferred to alcohol and preserved therein as is usually done.

When catgut has been treated with this alcohol-formalin mixture a very peculiar change as regards some of its properties will be found to have occurred. It does not become stiff or brittle, and even after boiling in water for some hours it loses practically none of its former strength, nor does it disintegrate in boiling water as is the case with catgut prepared by the methods generally in vogue.

The fact that it can be boiled without destroying it is very important for a number of reasons, but the three given below will suffice for present purposes.

It facilitates the complete removal of the irritating formalin from the catgut, as both formalin and alcohol are readily soluble in water.

Secondly, a more aseptic state of the gut is produced by the antiseptic properties of the formalin.

Lastly, it becomes still more surely aseptic as well as non-irritating from boiling in normal saline solution into which the spool of catgut can be put just at the beginning of a surgical operation and in this way avoid bringing alcohol, oil of juniper, etc., in contact with delicate membranes and other tissues.

The advantages gained from the employment of animal ligatures and sutures rendered positively aseptic by this method are obvious, so that further dissertation thereon is needless.

In conclusion, I would add that other animal substances, such as decalcified bone drains, bone buttons and rings, rings of catgut after Abe, etc., will give equally good results with the formalin method, and may be used on such occasions as require a not too early softening or absorption of the animal substance that is employed.

SCHELL: APPENDICITIS.

APPENDICITIS.*

By Walker Schell, M.D.,
Terre Haute, Ind.

The last word has not been written on this subject, nor is it likely that many questions of practical importance connected therewith will be formulated into rules for many years.

It is even possible that, notwithstanding the vast literature of the subject, many things have been overlooked.

It is peculiarly unfortunate for medicine that all the operations of the human mind cast themselves into the mold of some theory, and all facts are dominated by the evil spirit of hypothesis. Thus an a priori pathology has led the writers of our text-books to lay down a priori rules of treatment. This school of writers coined a multitude of terms to describe the location of inflammatory conditions in the right iliac fossa. We to-day understand that this refinement was unnecessary and without the basis of observation. It is sometimes with great relief that we turn away from the voluminous communication of some writing-desk theorist to the chefs d'œuvre of ancient writers on medicine. These classics of medicine are vast storehouses of facts founded on observation, hence the sage of Cos—the mighty Hippocrates—wrote not for one age or one country, but for all time and for all the generations of men. Practical men are breaking the idols of the theorists in the temple of thought nowhere more ruthlessly than in the field of abdominal medicine and surgery. All the hidden mystery of pathological condition must stand before our unveiled eyes open and understood. A less complete investigation does not satisfy the demands of modern science. We allow nothing to stop our investigations. This field of investigation is peculiarly American, and in America it received its first and therefore its chief impulse from the pioneers of the profession in Kentucky, Ohio, and Indiana. There need, however, be no apology from any one for carrying a lance into a free field, since so much is uncertain and so frequent are the mistakes of the most experienced men that any observation is worthy of record. One need only make a superficial examination of the vital statistics of our State to be convinced that many cases of appendicitis are still overlooked by the average practitioner, and the patients die without the chance of relief being offered them. If such is not the case, it will then be the duty of some experienced man to explain the meaning of the two hundred and thirty-one deaths from peritonitis for the statistical year ending October, 1892, and especially when we learn that

* Read before the Indiana State Medical Society.

† This preliminary treatment may be omitted if one so desires.
eighty-eight deaths were of males, sixty-two of whom were under forty years of age. It may be safely concluded that some of the one hundred and thirty-five cases returned as enteritis were unrecognized cases of appendicitis. Of course, in the case of children we should be little inclined to question the returns made to the health officers. The exceedingly common return, "inflammation of the bowels," is always open to suspicion. It is not intended, however, in this paper to in any way discuss statistics, and it is always dangerous to discuss inferential statistics, so that branch of the subject will be dropped with the remark that few experienced men doubt that many cases of appendicitis are in practice unrecognized.

The suspicion that every case of peritonitis in the male may be due to perforation of the appendix is just, although I present you a specimen of an appendix far short of perforation which caused a well-marked inflammation of the peritoneum that bade fair to become general even before perforation had taken place. Other causes of peritonitis and abscess in the right iliac fossa are not common.

For purposes of treatment it is not necessary that the surgeon should separate perforative and inflammatory affections of the cecum from those of the appendix. The apex of the cecum is usually found upon the psoas muscle, and it is well that we should remember that this is just within the middle third of the ligament of Poupart.

If you examine a large number of bodies you will find that the position of the cecum is not constant, and it may be even in the pelvic cavity. This last is a location which might cause diagnostic difficulties in the case of female subjects.

It is well, then, to remember that the appendix may be the cause of pelvic abscess, and it seems to me that there is just ground for believing that some of the reported cases where fecal material escaped from the fistulous openings of a pelvic abscess were in reality cases of perforative appendicitis. Sometimes the cecum is so mobile that the appendix is carried high in the abdomen, so that we might believe the liver or gall bladder to be the seat of the difficulty.

In a paper intended to be read in a few minutes little can be said about diagnosis. The prominent features of this disease must be ever in the mind of the physician, for it is a difficulty that he must frequently encounter, and the exitus lethalis may occur in twenty-four or forty-eight hours. The symptoms are, briefly: Sudden and violent pain in the right iliac fossa, aggravated by every movement and by the gentlest palpation; vomiting of green material; constipation; and the presence of a tumor the percussion note of which is dull, or dull tympanitic. Frequently the percussion note is clear at an early stage of the disease, because the appendix and the exudation are behind the cecum.

The pain often radiates, but this fact need not throw us off our guard. Especially do we elicit pain when we move the right thigh or press upon the abdomen at a point from five to seven centimetres within from the anterior iliac spine. Disturbances of micturition are very common.

The description of the minute anatomy of appendicitis is not found in any of our standard authorities. Patholo-

gists have studied the late changes of the disease. It has probably not been their fortune ever to examine carefully those of its inception. Frequently more is to be learned from the beginning than from late changes. It is therefore with peculiar pleasure that I present to this learned body of men some microscopical preparations which show the very beginnings of the disease. You will see the beginning of the destructive process in the glands. Some specimens which I have mounted show a single gland involved in the destructive process, others show four or five. There the infecting agent will gain access to a lymph vessel, and a little distance removed and beneath apparently healthy tissue you will see little pus pockets, the beginnings of abscesses. These are usually situated in the adenoid layer of the appendix, and, I am satisfied, frequently find their way into the interior. This accounts for so many fortunate cases where symptoms are threatening. On the other hand, the cicatrizing of these abscesses and ulcerations accounts for stricture and deformity, so frequently found where there is a history of relapsing appendicitis.

The number of glands in the appendix is so great that it may be regarded anatomically as a tubular agminated gland.

These glands do not escape irritation and the action of infectious poisons.

Next to the ileum the cecum and vermiform appendix are most frequently altered by ulceration and gangrene in typhoid fever. If you will take the trouble to examine in detail the records of post-mortem examinations after typhoid fever you will be surprised at the frequency of alterations in the appendix, and in a very large percentage of cases these changes are of the gravest character. You will find that a fair examination of the statistics will show it to be the seat of perforating ulcer in from ten to thirty per cent. of the cases where this lesion takes place in typhoid fever. In one case of appendicitis I operated successfully four weeks after apparent recovery from typhoid fever. The relation of typhoid fever to anatomical changes in the appendix has not been sufficiently emphasized, and possibly is not properly understood. To say the least, it presents an interesting field worthy of investigation.

Every one can call to mind cases of catarrhal or ulcerative changes of the cecum and appendix following typhoid fever which at the time were not understood or appreciated as a part of the disease, and where symptoms of a very annoying character were present long after the fever ended. Perforation of the cecum, except as a result of dysenteric, tubercular, or typhoid ulceration, is a very rare accident. There are cases, examples of the opening of an abscess, caused by changes primarily in the appendix, the opening in the cecum being the secondary process. This fact was not properly interpreted by the older pathological anatomists, hence the frequency of their use of the term typhilitis. It is true that ulceration of the cecum is not very uncommon, but it usually stops short of perforation, and the history is that of dyspepsia, decomposition of the contents of the bowels, and chronic constipation. The symptoms are far different from the exceedingly characteristic disease to which we have for convenience applied the term typhilitis.
The older writers on this subject laid great stress on the presence of foreign bodies in the appendix. The presence of altered fecal masses as a source of irritation of the appendix is common, but real foreign bodies are rare. In two cases where I have found these bodies at the autopsy I am now inclined to believe their presence was accidental.

In one autopsy held by myself and Dr. Allen Pierson, where the cause of death was perforative gangrenous appendicitis, we found a number of blackberry seeds in the appendix and some loose in the peritoneal cavity. I am not inclined to attribute to these bodies the same importance that we thought they possessed at the time. In this case the symptoms resembled very closely those of obstruction or internal strangulation. There were facial vomiting and obstinate constipation. These symptoms were due to peritonitis septica universalis. To avoid mistakes, every case should be thoroughly investigated. If the signs of perforative peritonitis are present the history of the case may throw much light upon the diseased conditions before us. Perforative peritonitis which becomes general is a most fulminating disease, and where we have reason to believe that a defensive barrier has not formed, we must act quickly if we are to do any good. There is absolutely no hope for the patient if we delay even a few hours. In consultation once with Dr. Jacob Coble at dusk on a winter’s evening we decided to wait until morning rather than undertake the operation by uncertain light in a log cabin. The diagnosis was plain but the symptoms had just begun and did not seem to be extremely urgent.

We returned the next morning in time to hold an autopsy, but too late for operation, as our patient had died during the night. There are cases where the general condition is so bad that operative interference seems absolutely unwarrantable, the slight shock of rapid incision and drainage proving quickly fatal. I have in mind one case, however, where the patient seemed moribund from the profound shock of perforation, but was rescued by rapid operation and a barrier of gauze that prevented further infection. In these cases we must step in and do our whole duty by the patient even at the loss of personal reputation.

In these cases our conduct should be absolutely selfless. In cases where Nature has erected a defensive barrier the operation must be done with much caution while the adhesions are yet weak, or harm will be done. It is still a question much debated in consultations and by no means settled as to the proper time for interference. When the case is seen immediately after perforation has taken place there should be no delay, but when Nature has once established her defensive barrier we may well fear that our manipulations might cause general infection of the peritoneal cavity.

The fear that these adhesions may give way on slight movement or any increased abdominal pressure, such as vomiting, is causing surgeons to accept the responsibility of operating even in cases doing well, since any accident might bring about a fatal result. Rupture of the abscess is not always unfortunate. I remember one case where a time of operation was appointed and preparations were made, when an hour or two before our returning to perform the seemingly necessary operation Nature made an opening into the bowel. A large amount of pus was discharged by stool, to the great relief of the patient, and the operation was declined. Recovery was uninterrupted, and so far as I know she has been comfortable since.

Exceptions can never be accepted as rules of practice, and in many cases our conduct would be wiser if they did not occur. The fact that this disease is not always of the grave character assumed for purposes of unity of discussion so far in this paper is known to all.

There is in practice infinite diversity of symptoms. In cases of catarhhal appendicitis to which the term typhlitis stercoralis is applied we have symptoms of varying severity. The severer forms have for practical purposes already been discussed as far as it seems to me profitable, since they end in deep ulceration and perforation. The symptoms of milder disease are often vague, and are principally flatulence, tenderness in the right iliac fossa, and pain in the right thigh. Constipation is usually present, and, if obstinate, leads to the accumulation of gases and altered contents of the bowel above the seat of the disease, which causes vomiting. These symptoms, sometimes very acute, subside after free movement of the bowels.

This fact has not escaped observation. It is a rule of sound practice to remove irritating ingesta, fermenting intestinal secretions, and fecal masses.

When this rule is applied to mild cases of typhlitis the result is highly satisfactory. There can be little objection certainly to the cautious use of enemata, except where the symptoms are so clear and so severe as to set at rest all doubts as to the nature of the disease and establish in the dullest mind the fact that perforation has occurred, when the use of enemata would be harmful and sometimes dangerous.

The stupid and blundering practice of giving cathartics in these cases can not be too strongly condemned. The resort to purgatives is so common that it must be rebuked in language that can not be misunderstood. It is in violation of common sense and results in disaster. What I have said of cathartics in general applies to saline in particular.

Active peristalsis even in the stercoral form of the disease aggravates the symptoms, not uncommonly increasing the vomiting and bringing on dangerous symptoms of intestinal obstruction, because the contents of the bowel can not be propelled through the inflamed and paralyzed section. In mild cases cathartics should not be used, because they are not needed, since Nature or a gentle enema can accomplish recovery without them.

Active peristalsis where the cathartic or saline is successful so far as securing movement of the bowels is concerned is also disastrous to the patient, because it breaks down and tears salutary adhesions, opens perforative ulcers that may be closed by inflammatory lymph, and spreads infection by movement of the intestinal coils which act as the defensive barrier to the general cavity of the peritoneum.

The surest way to fill the general cavity with fecal matter is to liquefy the contents of the bowel. If, therefore, you wish to destroy your patient, give him saline.
If it is too small to work in the dark, and are likely to break down defensive adhesions. It must be remembered that the abscess wall is made up of coils of intestine. Only when the walls of the abscess are very firm are we justified in irrigating. The introduction of fluids for any purpose in fresh cases is not good practice. It will spread the infection and break down barriers. It is a violation of the rules of antiseptic surgery.

Sterilized gauze may be gently used to cleanse the abscess cavity; but water should only be used in general septic peritonitis, where matters can not be made worse, and thorough flushing and cleansing may possibly offer some hope.

If any considerable amount of pus is present, provision for drainage must be made. A glass or rubber tube should be used, and the cavity well filled with iodoform gauze. If all goes well these may be removed and the wound closed by means of secondary sutures on the second or third day. These sutures should be placed in position at the time of the operation. The stump of the appendix should be covered by a flap of peritoneum, if possible. The appendix itself should be amputated close to the cecum, if this can be done without great difficulty.

If there is a mass of adhesions and the appendix is buried in the walls of the abscess cavity, no effort at its removal should be made, since the most important part of the operation is completed when we have opened the abscess, and anything further that we may do will only make matters worse and add to the danger of the patient.

Cases of relapsing typhilitis we shall frequently meet with, and in some of these cases the patient can not be much aided without an operation. The operation should be done after the symptoms have subsided, if the case presents such an opportunity. The history of the case and the conditions found upon thorough examination should amply justify the operation before it should be undertaken. We have no moral right to undertake useless operations, and there are no greater knaves in our profession than those conscienceless individuals who are ever ready with the knife. The welfare of the patient should be our only guide as to right conduct.

The motive which led me to write this paper should probably be stated, since the literature of this subject is already so vast that a paper should justify its bringing forth. My experience is doubtless that of the ordinary practitioner whose field of work is limited to the usual routine of the every-day practice of his profession. This I conceive to be its chief merit, since men of vast experience not uncommonly exaggerate the importance of this work, and seek to throw mystery and difficulty around their contributions to science. Many of our text-books are not so clear and lucid as it seems to me they should be on certain points connected with this disease.

I have endeavored to make emphatic certain phases of my own experience where our books leave us in doubt as to the right line of practice.

I wish, further, to encourage the ordinary practitioner to do this operation, since in that way only can it be of great value to mankind. Operations that can only succeed
in the hands of a few great experts are not worth much to the race.

This operation can and should be done by every well-qualified general practitioner. By wide use it can be of untold benefit in the saving of human life and in the alleviation of human suffering.

APPENDICITIS.
Rupture of the Sac and Escape of its Contents into the Abdominal Cavity.

By J. M. BLACK, M. D.,
KNOXVILLE, TENN.

While I recognize the fact that surgical procedure for the relief of appendicitis is no longer an uncommon feature, I desire to report another case to illustrate what can be done under the most inauspicious circumstances, as well as to refer to the opposition with which we meet not only among the laity but the profession as well.

On February 7, 1895, I was called in consultation to see Dr. H., aged thirty-nine years; weight, a hundred and thirty-five pounds; American, and with good family history. He had been suffering four days; persistent vomiting, colicky pains, tenderness in the right iliac fossa, and obstinate constipation, with previous history of diarrhoea. Patient was lying on the back, with right leg flexed, with flashes of heat and cold. The temperature was 102° and pulse 104. A tumor of the size of a hen's egg was easily recognized in the right fossa, with an inflammatory condition of external parts. I urged an immediate operation and hastily summoned Dr. F. B. Powers, Dr. H. W. Bright, and Dr. H. P. Coile, who concurred in the diagnosis and advice for immediate surgical interference, to assist me. The patient and family strenuously opposed an operation despite the fact that they were told the prognosis of rupture and death in a few hours. Another physician was sought by the patient, and he gave the following advice: "Five years ago I would have advised immediate operation, but now I advise you to let Nature take her course."

Two days later, at 9 a.m., on February 9th, I was hastily summoned to the bedside of the patient, whom I found in a dying condition; expression anxious; face pallid; pulse, 118, weak and flickering; temperature under tongue, 103°5. He had fainted at 1 p.m., with chills following. The tumor was absent, with diffuse abdominal tenderness. At the earnest solicitation of the patient, we agreed to offer him the last resort—abdominal section—despite the inauspicious surroundings and conditions. He was lying in a (surgically speaking) filthy basement room occupied by the entire family. We could not operate there with any prospects of success, so decided to remove him to a comparatively clean room upstairs. To accomplish this purpose we had to carry him around through the open air, with the mercury seven degrees below zero and snow about eight inches deep. Just as soon as possible, with the assistance of the above-mentioned surgeons, and by the light of two small kerosene lamps, the operation was begun. The appendix was found to be ruptured and the remnants packed with fecal concretions. From four to six ounces of foul fecal pus was burrowing in the peritoneal cavity. This was thoroughly washed out with hot distilled water, the appendix ligated and removed, and the stump closed by Lembert's suture.

Everything went well until the ligation of the appendix was reached, when the patient became pulseless and breathing stopped. The patient was considered dead on the table, when my worthy colleague, Dr. Powers, came to the rescue. Removing his hands from the cavity where he was grasping the blind gut, he surprised us with a hasty restoration of the vital functions by the use of a pair of uterine dilators introduced into the rectum and repeatedly dilating the splintiner ani. We are all familiar with this dilatation in chloroform narcosis, but with his permission I commend Dr. Powers' use of uterine dilators as the most speedy and satisfactory, especially in cases, as in this one, where it seemed impossible to introduce the thumbs.

After the patient's restoration to normal lung and heart action, the cavity was again thoroughly drenched, a drainage-tube inserted, and the wound closed with three rows of sutures—first the peritoneum, then the muscles, and lastly the skin.

The patient made an uninterrupted recovery. Two hours after the operation the pulse was 90 and temperature 102°.

The wound was not dressed until the third day. There was no discharge. The peritoneum and lower muscular layer were entirely healed and the tube was removed. There was some suppurition under the skin, due doubtless to infection from the pus as it was washed out of the cavity. On the seventeenth day the patient was walking around his yard, and on the twentieth day after the operation he walked a distance of a mile and a half to my office and was finally discharged.

NOTES ON A CASE ILLUSTRATING THE TREATMENT OF ECZEMA CAPITIS BY SALICYLATE OF SODIUM.*

By CHARLES E. LOCKWOOD, M. D.,
ATTENDING PHYSICIAN, DEPARTMENT OF DISEASES OF THE NERVES, OUTDOOR POOL, BELLEVUE HOSPITAL, NEW YORK.

Different observers throughout the world send out ideas, and these germs of thought seem to float in the mental atmosphere like germs in the physical atmosphere, until, finding a congenial soil, they take root and bring forth fruit. In illustration of this, during the past summer I was reading Dr. Alexander Haig's most interesting book on Uric Acid as a Factor in the Causation of Disease, and was struck with his special commendation of salicylic acid and its compounds as favoring the excretion of uric acid, and especially with the point emphasized by him, "that, as regards acute rheumatism, the salicylic compounds are powerful in curing the disease exactly in proportion to their power of eliminating uric acid; that, dose for dose, salicylates are most powerful in both respects, and are followed by salol and at some distance by salicin"; and his experiments and charts seem to show that, under the use of salicylates, we have to do with excretion and not with new formation of uric acid. It was just at this time that a gentleman consulted me for an annoying eruption on his forehead, and he gave the following history:

Mr. N., male, white, born in the United States, aged thirty-eight years, weight one hundred and ninety pounds, occupation sedentary, consulted me on June 14, 1894, complaining of a red, papular, scaly eruption on the scalp and forehead near the hair border, attended with most troublesome itching. He said it

* Read before the Medical Society of the State of New York at its eighty-ninth annual meeting.
had appeared about four years before; that at first it was very slight, but as time went by it became worse, until he could stand it no longer. He gave a history of having suffered from rheumatism from 1839 to 1884; but since the skin trouble began the rheumatism had disappeared. An examination of his urine, passed on rising in the morning, showed acid reaction; specific gravity, 1.030; no albumin: no sugar; microscopical examination developed nothing abnormal. A diagnosis was made of eczema capitis, and, in view of the rheumatic history, I prescribed as follows:

B. Acid. salicylic. 1 tspn.
Sodii bicarb. 1 tspn.
Glycerin. 2 yd.
Acque. q. s. ad 3/4 hj.

M. Sig.: Tablespoonful in water three times a day, and half a teaspoonful of bicarbonate of soda in carbonic-acid water twice a day.

Locally I advised that he sponge the eruption for ten minutes night and morning with the "black wash," afterward rubbing in the following ointment:

B. O! ol. pics. 3 hj.
Ungt. hydrarg. ammoniat. 3 vj.
O! rose. q. s. M.

On July 10, 1894, about a month after his first visit, the patient called and said the trouble on his head had improved after taking the medicine forty-eight hours. The appearance of the eruption was now not so red, but brownish in color and scaly, and I prescribed two drops of Fowler's solution of arsenic with one teaspoonful of bitter wine of iron after meals, onefortieth of a grain of podophyllin three times a day for five days.

July 31, 1894.—Eruption has almost entirely disappeared.

August 31st.—Patient writes, "I have not been bothered with it since you treated me."

Thinking Dr. Alexander Haig, of London, might be interested in this case, as bearing on the subject to which he has given so much attention—namely, "uric acid as a factor in disease"—I sent a history of the case and its treatment to him, and received the following reply:

"I am greatly interested in what you say about the treatment of eczema by salicylate of soda internally, as I have never used it for this trouble, and, strange to say, since I received your letter I have seen a patient who suffered from (gouty) eczema of the face, and who had obtained more relief from a mixture containing salicylate of soda than from anything else. In this case a considerable excess of animal food was being taken, and I have suggested some alteration."

Dr. Haig wrote me again subsequently that he would try the treatment in all cases of eczema that might come under his care, and I give the notes of this case to the society in order to draw forth the opinion of its members on this subject, and with the hope that others may be induced to give a trial to salicylate of soda in all cases of eczema with a gouty or rheumatic history.

It is of interest to note in this case that the eruption had existed for four years, and improved at once on the administration of salicylate of soda.

An Old Member of the Medical Society of the County of Kings, N. Y.—A dinner is to be given at the Montauk Club, in Brooklyn, on the 25th inst., in honor of Dr. Andrew Otterson, the oldest member of the society, under the direction of its entertainment committee.
MINOR PARAGRAPHS.

DIPHTHERIA-ANTITOXINE SERUM.

At a meeting of the Paris Hospital Medical Society held on March 29th, according to the Medical Week, Dr. Varlot referred to the fact that injections of antiphilophteric serum in doses of from five to ten cubic centimetres caused a rise of temperature of from 2·25° to 4·5° F. He said this rise was undoubtedly due to some "hyperthermizing substance" contained in the serum, and the problem before us was to isolate from the serum this principle that might become a source of danger. Dr. Le Gendre confirmed this experience. Professor Hayem referred to his former experiments and said: "Antiphilophteric serum obtained from a horse is necessarily toxic to man." This toxicity, he said, was due to albuminoid substances in which heat produced isomerie changes resulting in destruction of their noxious properties. Dr. Gouguenheim, while approving of the administration of antitoxine serum, said that it was entirely without effect, even in very large doses, in cases of hyperdiphtheria. Dr. Serestre stated that he had injected ordinary horse serum into four children suffering from non-diphtheritic sore throat, and that the injections had produced slight febrile reaction and within a few days eruptions similar to those observed after injection of serum from an "immunized" animal. The latter, therefore, and not the antitoxine itself, caused the untoward symptoms that followed the use of antitoxine serum.

ANTISTREPTOCOCCOUS SERUM.

The Semaine médicale states that Dr. Roger, Dr. Charrin, and Dr. Marmorek reported at a meeting of the Paris Biological Society held on March 30th that they had employed antistreptococcus serum in the treatment of cases of erysipelas and puerperal septicemia. Dr. Marmorek had administered an initial dose of ten cubic centimetres of serum, derived from horses or asses which had been rendered insensitive by the inoculation of a very virulent culture of the strepctococci, to forty-six patients suffering from erysipelas, all of whom had recovered. Dr. Roger and Dr. Charrin had treated two cases of puerperal septicemia, one case of erysipelas in a three-weeks'-old infant, and one case of pseudo-membraneous angina with this serum, and the patients had recovered without complications.

ITEMS, ETC.

The Society of Medical Jurisprudence.—The special order at the last meeting, on Monday evening, the 8th inst., was a paper by Dr. Cyrus Edson, entitled The Powers of Boards of Health.

The American Medical Publishers' Association will meet in Baltimore on May 6th, under the presidency of Dr. Landon B. Edwards, of Richmond. Medical editors, publishers, and business managers are invited to be present.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending April 18, 1895:

The following-named officers are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the Association of Military Surgeons of the United States, to be held in Buffalo, N. Y., May 21 to 28, 1895: Bach, Dallas, Lieutenant Colonel and Deputy Surgeon General; Harvey, Philip F., Major and Surgeon; Appel, Daniel M., Captain and Assistant Surgeon. They will proceed from their respective stations in time to reach Buffalo on May 21, 1895, and upon adjournment of the meeting will return to their proper stations.

The following-named officers are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the American Medical Association to be held at Baltimore, Md., May 7 to 10, 1895: Forwood, William H., Lieutenant Colonel and Deputy Surgeon General; Winn, Charles K., Major and Surgeon; Reed, Walter, Major and Surgeon; and Pilely, Harry O., Captain and Assistant Surgeon. They will proceed from their respective stations in time to reach Baltimore on May 7, 1895, and upon adjournment of the meeting will return to their proper stations.

Banister, William B., Captain and Assistant Surgeon, is relieved at Fort McIntosh, Texas, and is ordered to duty at Fort Omaha, Nebraska.

Pilcher, James E., Captain and Assistant Surgeon, is granted leave of absence for two months on surgeon's certificate of disability.

Reynolds, Frederick P., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month, to take effect upon his relief from duty at the U. S. Military Academy, West Point, N. Y.

Robertson, Reuben L., Captain and Assistant Surgeon, is granted leave of absence to and including July 3, 1895, on
which date his resignation has been accepted by the President to take effect.

The following-named officers will report in person to Dewitt Calvin, Major and Surgeon, president of the examining board appointed to meet at Fort Leavenworth, Kansas, on Wednesday, May 1, 1893, at such time as they may be required by the board for examination as to fitness for their promotion, and upon conclusion of their examination will return to their proper stations: Raymond, Thomas U., First Lieutenant and Assistant Surgeon; Snyder, Henry D., First Lieutenant and Assistant Surgeon; Smith, Allen M., First Lieutenant and Assistant Surgeon; Clarke, Joseph T., First Lieutenant and Assistant Surgeon.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending April 13, 1893:

Pickrell, G. McC., Passed Assistant Surgeon. Detached from the U. S. Steamer Newark, and granted three months' leave of absence.

Dunbar, A. W., Assistant Surgeon. Detached from the U. S. Steamer Vermont, and ordered to the U. S. Steamer Newark.

La Motte, Henry, Assistant Surgeon. Detached from the U. S. Steamer Newark, and ordered home and granted two months' leave of absence.

Bagg, C. P., Assistant Surgeon. Detached from the U. S. Naval Hospital, Mare Island, Cal., and ordered to the U. S. Steamer Monterey.

Society Meetings for the Coming Week:

Monday, April 22d: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, April 23d: Medical and Chirurgical Faculty of Maryland (first day—Baltimore); New York Dermatological Society (private); Medical Society of the County of Putnam (annual), N. Y.; Hunterdon, N. J., County Medical Society (Flemington); Litchfield, Conn., County Medical Society (semi-annual); Buffalo Obstetrical Society.

Wednesday, April 24th: South Carolina Medical Association (first day—Columbia); Texas State Medical Association (first day—Dallas); Medical and Chirurgical Faculty of Maryland (second day); New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Society of the County of Albany, N. Y.; Middlesex, Mass., North District Medical Society (annual—Waltham); Philadelphia County Medical Society; Gloucester, N. J., County Medical Society (quarterly).

Thursday, April 25th: South Carolina Medical Association (second day); Texas State Medical Association (second day); Medical and Chirurgical Faculty of Maryland (third day); New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Pathological Society of Brooklyn; Roxbury, Mass., Society for Medical Improvement (private—annual); Hartford, Conn., Medical Association (annual); Pathological Society of Philadelphia (conversational).

Friday, April 26th: South Carolina Medical Association (third day); Texas State Medical Association (third day); New York Clinical Society (private—annual); New York Society of German Physicians; Yorkville Medical Association, New York (private); Philadelphia Clinical Society; Philadelphia Laryngological Society; Cleveland, O., Medical Society.

Saturday, April 27th: New York Medical and Surgical Society (private); Worcester, Mass., North District Medical Society (annual—Fitchburg).

Births, Marriages, and Deaths.

Married.

Gaunt—Dickinson.—In New York, on Monday, April 15th, Dr. Thomas T. Gaunt and Miss Fannie R. Dickinson.

Hodenpily—Faiths.—In New York, on Tuesday, April 16th, Dr. Eugene Hodenpily and Miss Marie D. Pahys.

Died.

Birchhead.—In Newport, R. I., on Friday, April 12th, Dr. William Hunter Birchhead, in his fifty-sixth year.

Dedrick.—In Fall River, Mass., on Wednesday, April 10th, Albert Clinton, Jr., son of Dr. and Mrs. Albert Clinton Dedrick.

Siegel.—In Brooklyn, on Friday, April 12th, Caroline Isabel, daughter of Dr. and Mrs. Ferdinand Siegel, aged two years, four months, and twenty-three days.

Stare.—In Bellevue, Pa., on Saturday, April 13th, Dr. David L. Stare, aged eighty-three years.

Westbrook.—In Brooklyn, on Friday, April 12th, Dr. Benjamin F. Westbrook, aged forty-four years.

Obituaries.

Benjamin F. Westbrook, M. D.

In the decease of Dr. Westbrook, which took place at his home, in Brooklyn, on the 12th inst., the medical profession sustained a loss that will be felt far beyond the city of his residence. He was a copious and unusually accomplished writer, and such a man is always missed by a wide circle of readers. He had a peculiar aptness for didactic writing, and yet it was so imbued by a scrupulous regard for the full import of facts from all points of view that he never allowed facility of diction to lead him away from perfect accuracy and fairness of statement. He was a safe and at the same time an agreeable teacher, of a sort not over-abundant.

Letters to the Editor.

"WATER-BORNE CHOLERA."

4612 Easton Avenue, St. Louis, April 15, 1895.

To the Editor of the New York Medical Journal:

Sir: In one of your March issues appeared an exceedingly interesting contribution to the study of water-borne cholera, penned by Dr. George Homan, health commissioner of St. Louis. In relating the fearful ravages of the disease in the ranks of the Fifty-sixth Regiment, while en route from Helena to St. Louis, he points to the particularly frightful mortality in the rank and file of the detachment on board the Continental.
This steamboat carried a cargo of unrefined sugar, of which great quantities were eaten by the negro soldiers. The writer believes that there was a possibility of the sugar having been infected with the virus by means of the common house fly, which, as he says, shows a partiality for alpine dejecta and saccharine substances. From the data collected Dr. Homan arrives at the conclusion that this particular choleraic outbreak was due to the drinking of unboiled river water polluted by St. Louis sewage. The question arises, Why was the mortality among the soldiers who had eaten the sugar so particularly excessive? I think that we are able to assign to the sugar in this incident a different and perhaps better-defined rôle. It is a well-established fact that a "catairial" stomach will carry on the inversion of cane sugar into dextrose much more readily and rapidly than a healthy viscous. This is due to the mucus, which contains a special ferment sometimes called invertin. The introduction into the stomach of excessive quantities of sugar will invariably produce an active secretion of mucus, thus furnishing the proper means for its own digestion. The soldiers who yielded to their inborn craving for sweets succeeded in producing an artificial catarhal condition in their stomachs. The large amount of alkaline mucus offered no bar to the cholera virus taken in with the water, possibly drunk in larger quantities after the sugar meal. In the absence of the inhibitory powers of a normal gastric juice the virus may have started upon its pernicious activity within the walls of the stomach, bathed as they were in ropy, alkaline mucus. But, even assuming that this did not take place in the stomach, we must admit that the condition of that organ was most favorable to the passage of the totally unmodified virus into the small intestines which, by the very nature of their secretions, invite the development of microbicidal changes.

Edward C. Renge, M.D.

UNTOWARD RESULTS OF HYPODERMIC INJECTIONS.

MEXICO, MO., April 12, 1895.

To the Editor of the New York Medical Journal:

Sir: I see from the Journal of the 6th inst. that Dr. E. H. Wilson, chief bacteriologist of the Brooklyn board of health, has examined antitoxine from the same lot used in the Bertha Valentine case, and reports it free from deleterious ingredients. As the Brooklyn case of death from the antitoxine has caused quite an amount of comment, with your permission I will report a case which has been under my observation that may throw some light on that case. I have a patient who is an habitual user of morpbin sulphate, using about eight or nine grains a day, hypodermically. The patient is about thirty-nine years of age, and, considering the amount of the drug he uses, is in robust health and seems to suffer no inconvenience from the use of the drug, except when he introduces the needle in certain regions of his body, when he suffers the most intense agony, which I will now describe.

I have been called to see him on four or five different occasions. Within five minutes after introducing the hypodermic needle in the region of the musculo-spiral nerve in the arm or the external cutaneous in the thigh he would experience a most intense itching and pricking sensation all over his body, the skin over the entire body would become intensely red and hyperemic, the brain would become greatly congested, and the pupils widely dilated. These phenomena would last about eight or ten minutes, during which time the itching and pricking sensation would be so intense that the patient would be almost in a frenzy, scratching and clawing himself to get relief. The cerebral congestion would be severe and, as I stated before, the pupils widely dilated.

This would happen only when he introduced the hypodermic needle in a particular place, either in the arm or in the thigh, in the region of the nerves mentioned, as near as I could judge. The use of the needle at other times would cause no inconvenience whatever. I am convinced that the same amount of brain congestion that this patient suffered from, in a weak, anaemic person, whose blood-vessels had lost their tone, would result in apoplexy. My patient would state that his head felt as if it would burst open, and to relieve the intense pain in the head, due to the great influx of blood, I have had to make pressure on the carotid arteries. This is a plain statement of facts without any coloring, and may throw some light on the Brooklyn accident.

W. W. Warinner, M.D.

ANOTHER CASE OF REMARKABLE FORTITUDE IN BREAKING THE MORPHINE HABIT.

STATE HOSPITAL, MORGANTON, N. C., March 8, 1895.

To the Editor of the New York Medical Journal:

Sir: We had in this hospital some years ago a companion case to Dr. Hughes's, reported as Predominance of Mind over Matter.

A young woman belonging to a family noted for their strong opinions and unwavering adherence to the course which they thought proper and right, twenty-seven years old, the wife of a physician, himself a user of morphine, was admitted as insane, her eccentric nature having become more pronounced on account of her habit.

She had been using morphine by hypodermic injection for three years, with marked mental symptoms for some months previous to admission. The amount could not be ascertained, but must have been several grains daily.

One of my first professional services to her was to open an abscess on her arm, due to hypodermic injection, and then I saw the remains of scores of punctures on both arms.

When accused of using morphine she denied it and said the abscess had resulted from a dose, given by hypodermic injection to revive her from a faint.

While she was unquestionably insane, there was no loss of memory, her relations in every-day life were much as any sane person's would be, and she was abundantly able to call for anything she wanted.

With the idea that she possibly had morphine concealed and would call for a dose before her physical condition demanded it, I stimulated her freely and entirely withheld morphine until she should "weaken."

She suffered all the tortures that refinement from drug habits entails, but until this day she has not called for a dose, and denies the habit.

She made a mental recovery; for several years has been at home and, except for inborn eccentricity, is still well and so far as known has not resumed the use of morphine.

Isaac M. Taylor, M.D.

Proceedings of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of February 13, 1895.

(Concluded from page 381.)

Rapid Speech Development in an Adult following an Operation for Tongue-tie.—Dr. G. Hudson Makuen presented
a patient, a young man nineteen years of age, a farmer, who, up to within eleven months, had been utterly unable to use articulate speech in a manner which could be understood. He had been examined by local physicians and had made to believe that his trouble was of central or cerebral origin, and that nothing could be done for him. The feeling that he was thus cut off from this chief means of communication with his fellow had completely disheartened him.

He had attended public school with other boys, and with the aid of his friends at home had managed to make some progress in arithmetic and to acquire a very slight theoretical knowledge of our language. He had seemed to understand a little ordinary conversation, and had learned easy lessons in history and geography by having them read to him. He would attempt to talk and recite in school, but his teachers had to guess, for the most part, at the meaning of his jargon. The speaker did not recall a single word that was at all intelligible. The first time he had gone to Dr. Makuen's office he had not been able to make the conductor on the train understand the name of the station at which he lived, and after frequent attempts he had been obliged to write it out, which he could do very imperfectly, for his spelling was almost as bad as his speech.

With a history of this kind, and being deprived of that greatest of all means of mental development—speech—we would be prepared, the speaker said, to believe that the patient had acquired a reputation, even among those who knew him best, for listlessness and stupidity. Indeed, his aunt, with whom he had gone, had given up all hope of making anything of him; but the boy, discouraged as he was, had seemed determined to make one more effort, and he had been thoroughly in earnest.

Upon examination of his vocal and speech organs Dr. Makuen found only a slight nostril or nasal catarrh and some little hypertrophy of the faucial tonsils. Of course, he thought immediately of the probability of the patient being tongue-tied, but the aunt assured him that there was nothing of the sort. He found, however, that the patient could protrude the tip of the tongue scarcely beyond the outer margin of the lips. The tip had seemed a full inch or more too short, and, strange to say, the frenum had not appeared to be a very decided factor in holding it down or back; for in his attempts to protrude the tongue the frenum had not been greatly stretched. The trouble had seemed to be a muscular one, and this the speaker believed to be the case. The anterior fibers of the geniobrygomus muscle had been too short, and had prevented not only the protrusion of the tongue but any other free action of that member. The patient could elevate the back part of the tongue and make the hard G sound or the NG sound, but he could make no sound whatever which required the placing of the tip of the tongue to the roof of the mouth or the upper teeth. He had made the K sound for T and hard G sound for D. As an example, he said "ik" for "it," and when he had been asked about his parents he had said they were "gay"—meaning that they were dead. Furthermore, there had seemed to be no method in his speech; it had been a mere jumble of inarticulate and unintelligible sounds, and the expression of his face had been in perfect harmony with his speech—vacant, staring, meaningless.

The boy having been somewhat delicate, and his friends having decidedly opposed operative measures, the cause of the trouble having been doubtful, the speaker decided to study the case carefully before giving an opinion or recommending methods of treatment. He had given him some vocal exercises for a few days and had watched the results, after which he had clipped the frenum of the tongue well back. He had then put him in the hands of a teacher, who had given him, under his direction, several hours' vocal drill each day for several months, during which time he had made considerable improvement in sounds and words which did not require free action of the tip of the tongue. By that time Dr. Makuen had been convinced that the trouble had been entirely a local one, and that the boy was of more than average intelligence and well worth developing. He had then decided to divide the anterior fibers of the geniobrygomus muscle, and thus try to give to the tongue the necessary freedom of action. His people would not give their consent to etherization, for they had been skeptical as to favorable results from any measures whatever. The boy, however, had been desperate, and would submit to anything which promised relief. The speaker had taken the matter into his own hands, therefore, and with cocaine anesthesia he made an incision under the tongue of three quarters of an inch in the antero-posterior direction and one inch and a half from side to side. There had been considerable bleeding, which had been easily controlled, and, of course, there also had been some pain.

Each morning for five days thereafter, Dr. Makuen had broken up little adhesions which had formed, and had practiced slight lingual traction. On the morning of the sixth day the patient had been in a great state of excitement, and had complained of much pain, which he had referred to the region of his tongue and throat. The tongue had been greatly swollen, filling the entire mouth and protruding between the lips. He had had a temperature of 103°. The larynx had become involved to the extent of threatening suffocation, and the speaker had thought it would surely be necessary to open the trachea, which he had made all preparations to do, but after succeeding in giving him a brisk purge the inflammation had gradually subsided and the breathing had become less labored. The patient had been confined to bed for ten days, after which time he had practiced frequent lingual traction and vocal exercises directed toward a free action of the tongue. His improvement from that time on had been most wonderful.

Dr. Thorington said he would like the patient to pronounce the words anthropological and ethnological. The patient repeated them distinctly.

Dr. G. G. Davis said that it was an extremely interesting case, and an instructive one. As regarded the relative parts which the operative procedure and the painstaking instruction had played in bringing about the result, it would be extremely difficult to decide which of them had contributed the most. The part that the tongue played in speech was uncertain, and he doubted if it was ever very important. Of course, in a person who had talked, and then had been deprived of his tongue or part of his tongue, speech was still intelligible; but whether an individual who had had the tongue removed in infancy would learn to talk was indeed a question. In this case there might have been some anatomical condition that would cause limitation of movement of the organ, or acted as an obstruction to prevent his learning to speak, until, later in life, he had been able to undergo the systematic instruction which Dr. Makuen had ordered for him, which might in itself be instrumental in producing speech. He regretted that these means for overcoming defects of speech were not better known than they were among physicians. The simple division of a tendon might be followed by elongation; but in the case of the tongue the resulting scar tissue might restrict its movement still further. In this case there was a practical demonstration that the tongue was more movable. The report of this case was an encouragement to others to repeat this method in similar cases. He did not think that it was extremely rare to find cases where no device was able to afford relief; this was so where there was diff-
difficulty in pronouncing those sounds which were produced by the tongue held in contact with the roof of the mouth, it being sometimes impossible to place the tongue there.

Dr. Martin said the remarks of the last speaker were very pertinent to the question. He could not say which had been the greater factor in the development of speech in this case—the instruction or the operation. He was certain, however, that the one would have been of little value without the other, for during the three months immediately preceding the operation he had given the patient very careful drill, which had resulted in improvement on certain words, but in no improvement whatever on all those sounds which required a free action of the tip of the tongue. It had only been after the operation that he could give those sounds at all. The shortening which usually followed ecartiation had been prevented by free exercise of the tongue and by frequent traction. He could protrude his tongue three quarters of an inch further than before the operation, and he had acquired great facility in articulation.

Varicella Complicated with Gangrene of the Scrotum.—Dr. Charles D. Spivak read a paper in which he said that Jonathan Hutchinson had been the first to draw the attention of the medical profession to a complication of varicella characterized by the development of gangrene of the skin and deeper tissues at the site of the eruption. The rarity of the complication in general, and the exceptional features of the case which had come under his treatment in particular, justified him, he said, in reporting it.

The patient had been a boy of Russian parentage, aged two years, whose father and mother were healthy, with no scarlet fever or tuberculosis in the family, and with five other children all well and healthy. He had had no serious illness previous to the attack of chicken-pox. As the speaker had seen the patient for the first time only on the eighth day of the disease he had had to rely upon the data furnished by the parents, who had proved to be tolerably good observers and quite reliable. On November 25, 1894, the appearance of the chicken-pox had been noticed for the first time; on the 26th the child had become restless and had had fever; on the 27th the fever had increased, the child had been delirious, and the scrotum had become red and swollen. This state had continued until the 30th, when the swelling had extended to the left inguinal region; a black spot, the size of a pinhead, had appeared on the left side of the scrotum, and soon several others had formed a circle around the original one and had coalesced. On the following day another black spot had appeared, a little further to the left on the scrotum, and "before one had time to look at it," as the parents had expressed themselves, the process of deep necrosis and "eating up" had commenced. On December 3d Dr. Spivak had seen the child for the first time. The child had been well preserved and plump, as had been seen on a photograph and by its appearance, and he had been somewhat irritable. The penis, the scrotum, and the left inguinal region had been very much swollen and tender. The left side of the scrotum had been covered by blackish, muddily-looking crusts and detritus covering about two thirds of it and passing over the ischium to the right side. The smell had been very offensive. The crusts and detritus had been carefully removed and the tunica albuginea of the left testicle had been exposed to the view, thus showing that the gangrenous process had destroyed not alone the integument but also the dartos, the external cremasteric, and internal fascias, and the tunica vaginalis. There had been a distinct areola around the ulcer. The existence of pus in the inguinal region had easily been demonstrated by its fluctuation and also by the oozing from a very small spontaneous opening that had been found about half an inch from the scrotum. The temperature had been 101.6°; pulse, 110. Pressure over the labio had given pain, but the handling of the ulcer had been almost painless. Dr. Spivak had washed the parts with bichloride and had applied an iodoform-gauze dressing and a bandage. On the following day, when the handage had been removed, the ulcer had been found to present a somewhat better appearance, but was still angry-looking and covered with pus from the oozing aperture. The child had been anesthetized by Dr. Rachel Skidelsky, and introducing the groove director through the opening the speaker had laid open the inguinal region throughout its length, as was seen on the photograph. He had cleansed the wound thoroughly and packed it with iodoform gauze. (At this juncture the photograph had been taken, which showed the incision with the packing in it: the left testicle had been exposed, and there were many spots of dried up vesicles all over the body.) The ulcer had been dressed with bichloride gauze saturated in hydrogen dioxide, and a T-bandage had been applied. The ulcer had required a good deal of trimming of the dead tissues. Dr. Spivak had ordered two grains of quinine to be given in the evening and two grains in the morning. At that time he had noticed that three children in the same family had varicella in different stages of development. There had been no complications in the other cases.

On the following day the temperature had fallen to 99.2°; the child had slept almost the whole night, the first time since it had been taken sick; the ulcer and wound had been clean and the gangrenous process had been checked. The local treatment had been continued in the same way during the entire period of the regeneration of the scrotum, which had taken about thirty-five days. The repair was complete and admirable, as could be seen on the child, leaving only a star-shaped cicatrix. No internal treatment had been needed after the third day.

Dr. J. Abbott Cantrell said he regretted that Dr. Spivak had not given more of the history of his case. When Hutchinson had given the name varicella gangrenosa to this affection he had stated positively that it did not occur with any other disease than varicella, but since that time he had somewhat changed that opinion. Besides being witnessed in connection with varicella, it had been seen with miliaria rubra and lichen planus by Crocker and with purpura by Moore and Bichler. In addition to this it had been witnessed as an independent eruption by Crocker, Payne, Abercrombie, Bowley, and Elliot.

Withey Stokes had recorded it, in 1809, as a pemphigous gangrenous; Bazin had also thought it to be a pemphigus; and Carpenter had referred to a case under the title of pemphigoid varicella. Simon had recorded an example under the name of multiple caelode gangrene.

Its usual seat was at or near the buttocks, the inner and posterior portion of the thighs, although it might be witnessed on any portion of the body; thus, Bichler has seen it affecting the ma-stage process, the car having become involved in the destructive process later. Jamieson had witnessed a case affecting the head, the face, the back, and the right thigh.

It began as an erythematous spot, scarlatiform in character, and this had been seen in Staufoth's case to precede any other change by twelve hours. This was followed by a papule, a vesicle, a vesicul-pustule, or a pustule. These, one and all, rapidly changed into a pustule, and after it reached the size of a split pea, or even before it became of that size, it ruptured, and the formation of a crust resulted. The lesion at this time was surrounded by a reddish or pinkish-red, or even a livid zone. In a short time the crust began to separate, and after its completion the process generally terminated, although this was not always so. When the crust was removed three
was an ichorous, ash-gray mass or purulent secretion at the lower
of the ulcer, which had a ragged floor, the ulcer looking
like a punched-out sore—in fact, resembling the condition we
had when a vaccination pustule was at its height. When the dis-
case began, or was in connection with a vaccination, it was wit-
tessed first on the same arm, but not at the point of vaccina-
Constitutional taint seemed to have an influence upon
the aggravation of the disease, but this was denied by Hutchin-
son. Thus, in Payne's case the child had died of acute miliary
tuberculosis; Abercorn's had shown double pneumonia,
with recent pleuritis of one side; Howard's had shown dullness
on percussion, the little patient having died of pyemia, and the
autopsy had revealed abscesses in one lung, while two ounces
of pus had been taken out of the pleural cavity; in Bowley's
case the patient had died of convulsions on the day after dis-
charge.

The disease was supposed to be due to a parasite, although
a constant germ had not as yet been demonstrated. Ehlers had
found the Bacillus pyocyaneus in two cases, Kallinger had
found the Staphylococcus aureus albus in one, and still others
had been found. The prognosis was favorable without the in-
tervention of some complication, such as lung trouble; syphils
had a deleterious effect. The treatment must be upon the
strictest hygienic basis; the patient was to be supported and
given tonics as well as the best of food; locally, antiseptics
were to be freely employed.

Dr. Sprak said that he had simply reported his own case,
and had not intended to review the extensive literature of the
cases which he had collected; neither had he wished to discuss
the mooted questions in pathology. He reported his case on
account of three interesting points: 1. There had been only
one lesion in his case, while in all the cases reported hitherto
they had been multiple. 2. The size had been unusually large
—about the size of a silver dollar in circumference—as could be
easily judged from the photograph. 3. There was only one
case reported where the guttula had been mentioned as having
been affected, and no distinct reference to the serotum had
been made.

Book Notices.

The Physiology of the Carbohydrates; their Application as Food
and Relation to Diabetes. By F. W. Pavy, M. D., LL. D.,
F. R. S., Fellow of the Royal College of Physicians, etc.

It would be impossible to find a more competent teacher of
the physiology of the carbohydrates than Dr. Pavy, who has
devoted the labor of his life to the attainment of the knowledge
unfolded in the pages of this volume, which must stand as a
magnum opus of patient, careful, scientific investigation.

The author alludes to the fact that the carbohydrate prin-
ciples constitute by far the largest portion of organic matter.
They have their origin in the vegetable kingdom as a result of
the operation of solar influence, and primarily play a part in
the scheme of life of the vegetable organism, while secondarily
they enter either directly or indirectly into the food supply of
animals.

The carbohydrates comprise a class of bodies in which car-
bon is associated with different proportions of the elements of
water, and a basis of classification is founded on the relation
existing between the water and the carbon. There are three
groups: the amylloses, which present the lowest degree of
hydration, and include cellulose, starch, glycogen, and dextrin;
the saccharoses, that include maltose, lactose, and cane sugar;
and the glucooses, that include dextrose, levulose, and galactose.
Each of these is described, and reference is made to the behav-
ior of sugar with phenylhydrazine, giving rise to the osazones.
The transmutation of carbohydrates by increased hydration and
by ferment and protoplasmic action is considered in relation to
the operations of life.

The author reviews his recently announced discovery of the
glucose constitution of protein matter, which demonstrated
that in the construction of protein matter by the synthetic
power of protoplasmic chemistry carbohydrate matter was a
participating agent, and that the latter was susceptible of being
liberated again with the occurrence of disintegration.

He shows that it is not true that the liver during life is, as
has been alleged, in a more saccharine state than other parts of
the system; in the case of muscle the amount of sugar present
may be considerably beyond that found in the liver at the mo-
tement of death. In reality sugar exists as a normal constituent
of all the tissues and organs of the body. He further shows
that blood flowing from the liver does not contain more sugar
than that flowing to it; furthermore, sugar is present through-
out the whole mass of blood. There is no appreciable dif-
ference in the amount contained in arterial and in venous blood,
and there is not less in the blood of the portal vein than else-
where. There is no evidence of the disappearance of sugar
from the blood in its transit through the systemic capillaries,
assumed under the glycogenic doctrine to take place; and, cor-
respondingly, there is no evidence of the transport, as a func-
tional operation, of sugar from the liver to the systemic capil-
aries.

Referring to his paper, published in 1876, On the Recogni-
tion of Sugar in Healthy Urine, Dr. Pavy says to-day that the
amount of sugar in healthy urine is in proportion to that exis-
ting in the blood of the general circulation; the one is an index
to the other.

These studies show that the liver neither forms sugar to be
discharged into the general circulation, nor temporarily stores
up carbohydrate matter from the ingesta. Its office is an arrest-
ing one, furnishing a line of defense against the passage of the
carbohydrates in a free state into the circulation. In propor-
tion as the line of defence is ineffectual, sugar will reach the
general circulation and then the urine. Diabetes, therefore,
consists of a loss, or of more or less impairment, of the power
that naturally disposes of ingested carbohydrate matter, and
that prevents the latter from reaching the circulation in the
form of free sugar. In one class of glycosuria there is a loss or
impairment of the power of disposing of ingested carbohydrate
matter, and in another there is, in addition to this, an innate
condition attended with the splitting up of the proteids of the
body, with sugar as a cleavage product. The former may be
controlled by dietetic management, the latter only to a partial
extent. On the strength of these facts the author suggests ra-
tional methods of treatment.

In the last analysis the evidence adduced demonstrates that,
as a result of the operations of life, carbohydrate matter be-
comes transmuted to a lower state of hydration, is applied to
the production of protein matter, and finally is transformed
into fat.

This volume is a most valuable contribution to medical sci-
ence, and will enhance the fame of its author. It deserves the
careful study of every physiologist and physician.

A Treatise of the Diseases of the Ear, including the Anatomy
and Physiology of the Organ, together with the Treatment
of the Affections of the Nose and Pharynx which Conduce
Enlargement of the Prostate. Its Treatment and Radical Cure.

The author states that since he delivered the Hunterian Lectures at the Royal College of Surgeons two years ago, when he criticised the small progress made in the surgery of this gland in comparison with the general advance in surgery, material progress has been made in the field of surgical intervention. This progress he regards as largely due to the renaissance of the old view of the purely sexual character of the prostate.

Dr. Moullin does not believe that enlargement of the prostate requires treatment for its own sake, for there may be great hypertrophy with no physical discomfort; but as soon as the functions of the bladder are interfered with treatment of the hypertrophy is necessary. Delay in such cases affords no advantages, the longer the condition is left to itself the greater the risk of an operation.

The author indicates that the choice lies between the habitual employment of a catheter, the renewal of the obstruction by operation, and, when nothing else is available, the formation of another route of exit for the urine, or castration. He concludes that in ordinary cases catheterism is to be preferred, but he lays stress on the fact that habitual catheterism is not a cure for the complaint.

The class of cases in which prostatectomy should be performed includes those in which there are certain anatomical conditions that interfere with the function of the bladder and those in which the catheter has gradually failed to be of service. Where prostatectomy is impracticable an artificial urethra should be made.

The author considers that castration may be of service in cases where everything else has failed.

The volume gives an interesting survey of the most recent knowledge of the important part of man's anatomy.

This little book shows very creditable work by Surgeon-Captain Fink. Its principal object seems to be to bring prominently before the profession a modification of, or rather an addition to, the usual operation—viz., immediate laceration of the hyaloid membrane when this interferes with vision. After the cataract has been extracted it is the author's practice to hold up fingers to be counted. If the patient can not do this, one can see, on examining the eye carefully with a magnifying glass, a diffuse and deep haziness in the center. This hazy membrane he incises with a cystotome and always produces clear vision together with a slight loss of vision. This operation, he says, is far superior to a later operation for secondary cataract, an operation he very seldom now needs to perform.
BOOK NOTICES.—MISCELLANY.

[N. Y. Med. Jour.,

that it has been their aim in this systematization and condensation to form, as it were, a framework upon which the more detailed knowledge may be hung. As the author of the introduction says—used for its purpose and being kept in its place, the book is to be treated as a rude morsum.

MISCELLANY.

Nervous Disturbance of the Heart resulting from Influenza.—In the April number of the Practitioner Dr. A. E. San- som, of London, publishes an article on this subject in which he remarks that during the febrile period the contractions of the heart are usually quickened, but by no means invariably. The signs and the symptoms, he says, referred to the heart in cases under his own observation have been distributed as follows: In twenty-three cases, pain referred to the heart; in thirty-seven cases, the rapid heart; in twenty-five cases, the irregular heart; in five cases, the slow heart; in ten cases, organic disease of the heart. The latter, as a direct result of influenza, the author believes to be very rare. The specific poison, he says, alarming re-enforces pre-existing rheumatic disease. Endocarditis and pericarditis of rheumatic origin may rapidly increase if the patient is attacked with influenza. In very rare cases a septic form of endocarditis has been begun by the acute disease. Acute and subacute inflammations of the aorta, and probably of the pulmonary artery, have been induced in some cases. Dr. Sansom says that he has no evidence, however, that endocarditis (except of the necrotic form) or myocarditis is produced by the toxic agencies of the disease. Disturbances of the nervous mechanism of the heart, however, are frequent sequel of influenza, and from a series of cases in which such disturbances have been manifested and from the associations with other cases in which there have been incontestable signs of disease of the spinal cord, he can not doubt, he says, that the disorders in question have their origin in in- duced morbid conditions of the medulla oblongata, the nerve elements within the spinal cord, and the sensorium. The pain which seems closely associated with the heart itself may be felt in the situation of the apex, over the anatomical site of the right and left ventricles, over the sternum, or localized in the intercostal spaces, especially the second, close to the sternal border. In some instances there is a sensation of fluttering of the heart (tremor cordis), but in most cases the heart sounds are normal; and the rhythm during the extremity of the pain, as well as at all other times of observation, is quite regular. Very commonly there is a sense of extreme mental apprehen- sion with fear of death. The pain may be continuous for hours, with exacerbations and mitigations, or paroxysmal. In
either case it may be of intense severity, and he has had several
instances in which it caused complete unconsciousness from
syncope. Naturally, he says, the fear of angina pectoris oc-
curs, but, happily, in the great majority of cases there is com-
plete recovery. The signs of high arterial tension are not
manifested. A favorable prognosis is, therefore, usually justi-
fied, and it is important that this good medicine of hope should
be administered to the patient, and that all depressing emotions
should be avoided. There may be an error, however, on the
other side. It is not correct to call these cases hysterical—the
symptoms may occur in the strongest men and in those who
present no associations with hysteria. In one case which he
observed, that of a lady in whom hysteria might have been sus-
spected from the symptoms, sudden death, preceded by convul-
sion, took place during the night. His diagnosis was acute or
subacute arthritis. The attacks of pain may begin to be mani-
fested very soon after the acute onset of influenza, but in many
cases the first symptoms do not occur until after the lapse of
several months—at least six months—from the acute attack.
Practically we should consider them as neuralgic; they are
often attended with distinct signs of neuritis, though the mani-
festations are periodic and not persistent. The distinction from
the dangerous condition of inflammation of the aorta is to
be made chiefly by observation of the effect of effort. Usually
the patients are able to walk about, and the attacks are not de-
termined by muscular exertion, although movement may aggra-
vate the pain when once established. In aortic inflammation
the pain as well as dyspnea is brought on by even slight move-
ments.

In any case of severe heart-pain after influenza complete
rest should be recommended in the early stages of treatment.
A hypodermic injection of hydrochloric of morphia (from a
quarter of a grain to a third of a grain) may be administered at
the situation of the maximum of the suffering, but the precau-
tions should be taken of giving a diffusible stimulant by the
mouth shortly before the injection. The author suggests the
following formula: Spiritus aetheris, 3 ss.; spiritus ammonio-
co., 3 ss.; tinct. sambul, 5 ss.; aqua camphora, 5 jss.; to be
taken as a draught before the administration of morphia, and
repeated an hour afterward. Once the severity of the pain is
thus mitigated, he says, other agents than morphia should be
employed. Quinine in doses of five grains dissolved in hydro-
bromic acid, as before suggested, is often very effectual. If
there is any periodicity about the attacks, this dose should be
administered about half an hour before the usual period of on-
set, and repeated at hourly intervals during the painful phase
until three or four doses have been taken. Smaller doses are
ineffectual. The same precautions as to the administration of
stimulant antispasmodics should be taken with quinine as with
opium, for quinine may depress the heart. After the adminis-
tration of quinine in these doses for three or four days there
should be a two or three days' interval. When, however, the
severity of the pain is broken a dose of five grains once every
two or three days is found to be sufficient. For more continu-
ous treatment at the early stages of the painful phase bromide
of sodium in doses of twenty grains with three minimis of Fow-
ler's solution, dissolved and sufficiently diluted, may be given
with advantage three times a day after food. In some cases
doses of five grains of iodide of sodium are added with benefit.
The bromide should not be given continuously for more than
two or three weeks; afterward the alkaline carbonates with
the small doses of arsenic may be substituted.

Local treatment, says Dr. Sussom, in the more persistent
forms of pain is valuable. Mustard poultices, sprinkled with
tinctures of opium, belladonna, and acouite, give relief in some
cases. He has used in others a fomentation of lint soaked in a
hot solution of salicylate of sodium with much advantage; or
an ointment containing twenty per cent. of salicylic acid and
ten per cent. of menthol in a fatty basis of kaolin and lard may
be rubbed in by a flannel pad over the painful area. In the
more chronic cases small oval blisters applied over the inter-
costal spaces have been efficient. He has also found the con-
stant galvanic current (as from a Schall's six-cell battery, the
positive pole placed over the nape of the neck and the negative
over the painful site, the applications being for ten minutes
twice daily) completely remove the pain.

Abnormally rapid action of the heart may be the immediate
sequel of an attack of influenza, or may be manifested some
months after the initial attack. In some of these cases palpita-
tions are severe, and the heart's action is made still more rapid
by muscular movements or slight causes of disturbance. In
very many, however, the abnormally rapid contractions of the
heart, habitually over a hundred a minute, are quite unper-
ceived by the patient. In a large number of cases there are
some of the associated signs of Graves's disease. One sign,
slight in itself, is worth investigation. The patient after
the attack of influenza may be observed to present some retraction
of each upper eyelid, so that the eyeball seems to be somewhat
unusually prominent; when the patient is asked to gently close
the eyelids it will be seen that both lids exhibit a very usual
trouer. There are, in fact, slight Stellwag's signs with spasm of
the orbicularis palpebrarum. In some instances there are all,
or nearly all, the chief phenomena of Graves's disease.
Where the lid signs are present, although even in a slight de-
gree, there will usually be found an undue rapidity or an irreg-
ularity of the heart's action. In the cases manifesting the
rapid heart there are often emotional outbursts. There may be
muscular tremors, flushing, perspiration, and faintness.
In many instances there are paroxysmal attacks characterized
by flatulence, nausea, gastralgia, and diarrhoea, accompanied by
dyspyrexia as well as palpitation—a combination which the author
terms a "vagus storm," as they seem to imply a disturbance
involving all the areas subserved by the pneumogastric nerve
He thinks that the condition of rapid heart after influenza
is explained by the effect of the toxines of the microbes upon
the nervous mechanism of the cardiac reflex. The vagus-con-
trolling influence is weakened, and the accelerator agencies are
relatively in excess.

In the treatment of these cases he believes digitalis and the
analogous cardiac tonics to be not only useless but dangerous.
The reasoning thus expressed: "The heart's action is rapid,
digitalis slows the heart's action; therefore give digitalis," is
unsound and unsafe. It seems to him very probable that in
these days, when digitalis, strophanthins, and other powerful
agents of their class, are readily procured in almost any quan-
tity by the public, are presented in an attractive form, and are
swallowed when not prescribed by a qualified medical practi-
cioner, many lives have been shortened. The first indication in
treatment is to allow all inordinate nervous perturbation.
It is not necessary, save in exceptional cases, to insist on complete
rest in bed, but all causes of undue excitement must be avoided.
The mixture of sodium bromide with small doses of arsenic, as
suggested for the treatment of pain at the heart, is perhaps the
most generally useful. During the periods of dyspepsia the
alkaline bicarbonates, with bismuth and small doses of dilute
hydrocyanic acid, seem to be the best therapeutic means.

For the treatment of the insomnia, he thinks the most use-
ful and least harmful agent is chloralhydrate in doses of twenty
or twenty-five grains administered at bedtime. If this is insuffi-
cient, the same quantity of sulphonal may be given. Opium, he
says, should be avoided, or, at any rate, reserved for emergen-
cies.
It is to be remembered, says the author, that an abnormal frequency of the cardiac contractions may be continued in a given subject for many years. We feel that such a patient is unstable, although there may be no other notable deviation from health. Treatment by drugs often fails to reduce the rate of the pulsations. He has observed a sufficient number of cases to convince him that in the continuous galvanic current we have a valuable method of treatment for these cases. The current from a Schall's four- or six-cell battery is sufficient. One pole, the anode, moistened with warm water or salt and water, is held over the nape of the neck, and the other, the cathode, is gently pressed into the groove in the neck outside the larynx. The current is allowed to pass for six minutes three times a day, the applications of the cathode being to the right and left sides of the neck alternately. In many cases the effect is quite imperceptible, but in some, even with these weak currents, there are effects upon taste and upon vision (flashes of light, etc.), and often there are prickings of the skin. The rate of the heart's pulsations is reduced, though it must be remembered that satisfactory results are very slow in appearing. There is seldom improvement in less than six months, he says, but he has seen the best results follow this plan of treatment.

The irregular heart after influenza has associations very similar to those of the rapid heart. The irregularity may be extreme, and yet unperceived by the patient. It is most important that attention should not be drawn to it, for, once observed as a subjective sensation, the previously almost harmless phenomenon becomes a lasting misery. There are with the irregular heart associations with the signs of Graves's disease, with vagus storms, and with multiple neuritis, as with the rapid heart. The most important differences are that the condition of irregularity of the heart's action is much more frequently attended with precordial pain and cardiac discomfort, that it is more apt to be shown in persons of advanced age and of gouty tendencies, and that it is less frequently co-exists with disturbances of the faculty of hearing. The lines of treatment are chiefly those recommended for pain at the heart and for tachycardia.

The treatment for gout, and for dyspepsia in general, becomes in these cases of still more importance than in the former, and judicious management of the nasopharyngeal passages (whereby reflex causes of irritation are removed) as well as of all forms of auditory disturbance, is to be carried out.

Abnormal retardation of the rate of the heart's contractions (bradycardia) may also follow an attack of influenza, and that immediately or after the lapse of several months. The slowing of the heart may be paroxysmal or persistent. Dr. Sansom has observed a case in which a pulse habitually of 72 a minute was reduced to 48 during periods of severe epigastric and abdominal pain, recurring every afternoon for three or four hours for the space of a week. After the pain had disappeared the pulse rose to a rate of about 90. Treatment with phenacetine and camphor, with local warmth and counter-irritation of the epigastrum and abdomen, is successful. Aperients and so-called appeals to the liver are seldom called for. If there is constipation, a dose of castor oil or an olive-oil enema is to be recommended.

A more permanent bradycardia is much more serious. The author has known a pulse of 19 a minute to follow an attack of influenza. During long observation of the patient in hospital, the pulse-rate never rose above 30. The man was discharged from the hospital in fair health, but died suddenly at his home soon afterward. The only drug which causes any increase in the frequency in such cases, according to his experience, is belladonna. The tincture may be given in doses of ten minims three times a day, or the extract in half-grain doses. The administration should be suspended for one or two days at the end of each week. Massage and graduated muscular exercises are useful; but it must be realized, he says, that the condition of very slow heart is one of peril.

The Employment of the Membrane of a Hen's Egg in Grafting.—In the Journal des praticiens for March 23 there is an abstract of an article on this subject which was published in the Archives de medicine militaire for March, 1885, in which the author, M. Amat, gives an account of the case of a young boy whom he had treated for a large burn caused by boiling water in the dorso-lateral region of the right foot. Repair was slow, and the author advised Reverdin's and Thiersch's method of skin grafting, but the family was very much opposed to it. M. Amat then thought it would be well to employ the exceedingly vascular internal layer of the membrane of a hen's egg. He made the attempt and obtained successful results. In 1888 and in 1893 he had the same success in the treatment of burns on the arm, the back, the feet, and the leg. In summing up his observations and those of others M. Amat found that good results had been obtained in nine cases and failure in seventy-four cases, as regarded the anaplastic value of the membrane of the shell.

These favorable results, says the writer, may be attributed to the "action of vicinity" of the graft on the evolution of the embryonic tissue, and not to its nature. There are therapeutic indications for its employment, especially in children, women, and nervous persons. The technique of this operation is as follows: 1. The membrane should be taken from a very fresh egg, as physiological observation has shown that the latent life of this membrane is then more active. 2. Grafting must not be done until the dressings have suppressed the suppuration and provoked a healthy growth. Previously to the transplantation, contact with the air must be avoided by a thick dressing of gauze saturated with a carbolic-acid solution. 3. Take a very fresh egg, break it in the center, empty it of the contents, and seize the membrane with a mouse-tooth forceps at the large end of the egg—that is, the internal layer of the membrane of the shell. 4. This layer is cut into strips about four or five millimetres in width and of the same length. These are applied on the wound with the point of a pair of scissors, and laid on their aluminous surface. 5. They are applied at a distance of from twelve to fifteen millimetres and are covered with a small square of tin foil and then by a dressing of gauze saturated with a solution of carbolic acid.

This heteroplastic procedure, says the writer, is worthy of attention, especially from practitioners who do not always have at hand the proper material for "inter-humain" or "inter-zoo-humain" heteroplasty. From this point of view it is interesting to make a trial of this procedure in rural practice.

The Comparative Value of Trional, Chloralose, and Somnial.—The Presse médicale for March 23 publishes an article in which the writer refers to the recent researches of a Russian physician, M. Kulemowski, who has studied the comparative value of these drugs and observed their action in lunatics, in neurasthenics, and in healthy persons suffering from insomnia. In France also, he says, the new hypnotics have been the subject of interesting works, and at the last meeting of the Société médicale des hôpitaux M. Galliard made an important communication in regard to trional. With regard to the harmfulness of this drug, says the writer, there are various opinions, as serious troubles have been observed after a prolonged use of it. To avoid its accumulation M. Kulemowski gives it at intervals of two days, and not more than thirty grains a day. The hypnotic effect varies according to the class of pa-
In those who have no psychic disorders a dose of from twenty-two to thirty grains is sufficient to produce a quiet sleep; this dose gives rise immediately after its administration and when the patient awakes to the same troubles that sulphonal does, but it never causes circulatory, respiratory, or digestive troubles, although in some cases it is used for a year, and in this respect it has a real advantage over sulphonal. In lunatics suffering with insomnia, in those with chronic psychic disorders it acts better; in other cases, however, it acts slowly, often not until the following night. It always quiets maniacal excitement and alcoholic delirium; but it has a very bad action in melancholia and in hypochondria, as it increases the nervous depression. It must not be given, either, in cases of cerebral neurasthenia, as it accentuates the atony and the depression. Although trional is eliminated more rapidly than sulphonal, it may, however, become accumulated in the organism and cause serious troubles, although, if precaution is taken not to employ it continuously, but at intervals of two or three days, there is nothing to fear from its use, and it may be given in even stronger doses than from fifteen to thirty grains, especially in delirium tremens, where it produces very good effects.

Chloralose presents one very important defect, and that is that it occasionally provokes toxic symptoms which manifest themselves by an exaggeration of the reflex excitability of the medulla amounting almost to convulsions; in addition to this it is very difficult to decide upon the proper dose, as its action varies not only in different persons, but even in the same person. It seems, however, from observations made by M. Khmelewsky in cases of different forms of lunacy and in others of psychic troubles, that frequently the dose of eight grains is sufficient to produce quiet sleep. In cases of secondary psychosis without much agitation the hypnotic effect may be obtained with six grains. If the dose of ten grains is exceeded, toxic symptoms are observed in the majority of cases and in subjects, too, whose nervous system is normal. These symptoms may appear also after the use of smaller doses in weak, hysterical, or alcoholic persons. In other forms of psychological or nervous disorders doses of from four to eight grains of chloralose rarely give rise to accidents. These toxic symptoms are convulsions more or less generalized, and they are accompanied by involuntary emission of urine; but, notwithstanding their apparently alarming character, they disappear rapidly and do not give place to any serious or lasting nervous troubles or to any painful sensations.

Somnal, says the writer, has been recommended by some German authors, and M. Marandon de Montyel, in the Annales médico-psychologiques for August, 1895, also recommends its employment, from which he has obtained excellent results in patients affected with acute melancholia. Not only has it produced sleep, but even recovery after three or four weeks of its daily employment in doses of from seventy-five to a hundred and five grains. In other subjects somnal provokes a certain degree of intoxication before sleep, agreeable dreams during sleep, and a slight excitement and gaiety on awakening.

Khmelewsky has endeavored to verify the results obtained by M. Marandon de Montyel, and has found that there is a very marked amelioration in cases of melancholia. In healthy subjects doses of from thirty-eight to forty-five grains give rise, at first, to a slight intoxication; half an hour after its administration sleep follows, although it is often interrupted. From forty-five to sixty grains produce very profound sleep. On awakening, there is no disagreeable sensation, as is the case when trional and sulphonal are used. M. Khmelewsky has not observed any particular gaiety or excitement in the patients, as M. Marandon de Montyel had alleged. In melancholia, as well as in simple insomnia, says the writer, somnal always acts better than any other hypnotic, for not only does it induce an agreeable and profound sleep, but it is not accompanied by disagreeable subjective symptoms on awakening; it causes no depression, as sulphonal and trional do; it does not give rise to the motor troubles so frequently seen after the use of chloralose; and it never produces cardiovascular accidents. It is only in cases of gastro-intestinal disorders that the use of somnal is contraindicated, as it may aggravate dyspepsia and diarrhoea.

It is interesting, says the writer, to compare M. Khmelewsky’s conclusions in regard to trional with those of M. Galliard, bearing in mind the fact that the observations of the Russian physician relate principally to lunatics, while M. Galliard’s were among subjects attacked with acute or chronic tuberculous disease, those with cardiac affections, etc., who were suffering with insomnia.

Both M. Khmelewsky and M. Galliard were of one opinion in regard to the harmlessness of trional; that it did not provoke any disorders of the circulation, the respiration, or the digestion, and that the sleep it produced was peaceful and without dreams. They differed, however, in regard to the awakening, which, according to M. Khmelewsky, is often painful; on the other hand, M. Galliard maintains that it is often agreeable and rarely painful. They also differ as to the rapidity of its action. M. Galliard says that sleep is produced in from twenty to twenty-five minutes after its administration, while, according to M. Khmelewsky, it takes from two to three hours (in excited patients, it is true), although the doses given are large, from twenty-two to thirty grains.

With regard to chloralose, says the writer, one is impressed with the size of the doses employed by M. Khmelewsky, who gives them without fear of serious toxic accidents. While bearing in mind the idiosyncrasies relative to this hypnotic, not only in different subjects, but in the same subject under different circumstances, he speaks casually of doses of eight or ten grains or more.

The practical conclusion, says the writer, that may be drawn from the discussions which followed the communication of these observations is that, if good results are to be obtained from the use of chloralose, it must not be administered except in very moderate doses, beginning with a grain and three fifths and increasing them progressively from two grains and two fifths to three grains and a fifth.

The Association of Military Surgeons of the United States.—The fifth annual meeting will be held in Buffalo on May 21st, 22d, and 23d, under the presidency of Surgeon-general George M. Sternberg, of the army. The programme includes the following addresses and papers: An Address of Welcome to the City of Buffalo, by the Hon. Edgar B. Jewett, of Buffalo; An Address of Welcome to the State, by the Hon. Levi P. Morton, of New York; An Address on Behalf of the Medical Profession, by Dr. Roswell Park, of New York; The President’s Address, by Dr. George M. Sternberg, U. S. Army; The Report of the Committee of Arrangements, by Dr. Albert H. Briggs, N. G. N. Y.; A Report on the Status of the National Guard, by Dr. Nelson H. Henry, N. G. N. Y.; Experiments Illustrating the Degree of “Powder Burn” as Modified by the Distance of the Object, Size, and Conformation of the Bore, Amount and Standard of the Powder, and Other Practical Demonstrable Causes, by Dr. Louis A. La Garde, U. S. Army; The Location and Removal of Missiles from the Cranial Cavity, by Dr. George R. Fowler, N. G. N. Y.; A Discussion of the Report of the Committee on “Litter,” by Dr. John Van R. Hof, U. S. Army, and Dr. E. T. T. Marsh, N. G. N. Y.; Ambulance Construction, by Dr. Dallas Bache, U. S. Army, and Dr.
Charles E. Greenleaf, U. S. Army; Conservative Surgery on the Battlefield, by Dr. Nicholas Senn, Ills. N. G.; The Relation of Concentrated Fuel to Active Service Demands, by Dr. Charles Smart, U. S. Army; The Location of Sites for and the Construction of Military Posts in Relation to Proper Sanitation, by Dr. Dallas Bache, U. S. Army; The Relation of Naval Architecture to Proper Sanitation, by Dr. J. R. Tryon, U. S. Navy; On the Value of Bronium in Military Surgery, by Dr. M. O. Ttery, State of New York; The Handling and Care of the Wounded on Shipboard, by Dr. A. C. H. Russell, Dr. E. R. Stitt, and Dr. A. M. D. McCormick, U. S. Navy; The Post Exchange from a Medical Standpoint, by Dr. Philip F. Harvey, U. S. Army; Infected Bullets, by Dr. Louis A. La Garde, U. S. Army; Fifty-two Amputations of the Thigh, by Dr. John D. McGill, N. G. N. J.; Instruction of the Hospital Corps, by Dr. H. S. Turrill, U. S. Army; Upon the Surgeon General of the Militia, by Dr. George Cook, N. G. N. J.; Field Hospital Service, by Dr. Dallas Bache, U. S. Army; Some Experimental Work with the New Ball, by Dr. J. D. Griffith, N. G. Mo.; Gunshot Wounds of the Kidneys, by Dr. A. L. Wright, N. G. Iowa; On the Travois Litter, by Dr. Wladimir F. De Niedman, N. G. Kan.; Details Regarding the Medical Service of the National Guard of the State of New York during the Buffalo Strikes of 1898, by Dr. Lewis Bales, N. G. N. Y.; Details Regarding the Medical Service of the National Guard of the State of New York during the Recent Brooklyn Strikes, by Dr. William E. Spencer, N. G. N. Y.; Details Regarding the Medical Service of the National Guard of the State of Illinois during the Recent Chicago Strike, by Dr. Charles Adams, Ills. N. G.; Method of Caring for the Wounded on the Field and in the Hospitals of the Chinese and Japanese Armies, by Dr. C. U. Gravatt, U. S. Navy; A Consideration of Scorbutic Manifestations in Young Subjects, by Dr. John C. Wise, U. S. Navy; Asepsis in Military Service, by Dr. Eduard Boeckmann, N. G. Mimm.; A Medical Officer in the Volunteer Army, by Dr. F. W. Byers, State of Wisconsin; The Merriam Pack, by Dr. Lewis Bales, N. G. N. Y.; Measures for the Prevention and Suppression of Dangerous Contagious Diseases in Garrison and in the Field, by Dr. H. Lincoln Chase, Mass. V. M.; A Report on the Diagnosis Tag for Field Use, by Dr. William H. Fowood, U. S. Army.

The Advantages of Amputation without the Use of a Tourniquet when the Vessels are Atheromatous.—At a recent meeting of the Philadelphia Academy of Surgery Dr. De Forest Willard read a paper in which he said that the disadvantages of the use of the tourniquet when the vessels were atheromatous were obvious. The constrictor not only caused minute fissures in the walls of the vessels, but it might even fracture them, and in either case it tended to develop arteritis, subsequent loss of vitality in the flaps, and secondary gangrene. At the same time the patients presenting this condition were frequently old and feeble persons who were seriously exhausted by the local condition of gangrene, presenting other evidences of obstructed vessels, and could ill afford any loss of blood.

Gangrene occurred most frequently in the feet and legs, and for such a condition amputation in the neighborhood of the knee joint, or at the thigh, was advisable, since after leg amputations the diseased conditions frequently returned.

Amputation through the knee joint could be performed with less hemorrhage than at any other portion of the limb, since in the neighborhood of the knee all the vessels in front were small and could be readily caught with haemostats as the anterior skin flap was cut. The tendo patellae and the lateral and posterior ligaments could all be divided without serious hemorrhage. We then had the limb hanging by the posterior bridge of soft tissues, which bridge contained the large vessels, and could be easily caught by the fingers of an assistant; in fact, it was now a perfectly simple matter to expose the popliteal artery and to test its pulsation to discover whether it was actually perivous, then to expose it just enough to carry around it a bundle of cutgut ligatures, four or five, which ligatures were tied just sufficiently tight to bring the inner coats of the vessels together and not to crush them.

Sometimes the popliteal artery would be found thoroughly plugged, making it necessary to work up in the posterior flap for a considerable distance before a perversus vessel would be found.

The popliteal having been tied, the flap was firmly grasped to control the smaller arterial branches, and the posterior flap quickly cut of the desired length. The operation was practically bloodless.

Should the artery be impervious, it might be necessary to do an amputation higher than the joint itself. The tissues now could be pushed back and the periostium divided above the condyles and stripped back from the femur to the desired distance without loss of blood and without injury to the soft tissues. The femur was then divided opposite the point of ligation and the wound dressed antiseptically.

By this stripping back the tissues subperiosteally an amputation in the lower third of the thigh could be performed with but little loss of blood and without injury to the vessels by any form of constricting band. It was a plan equally well adapted to traumatic cases with atheromatous vessels. The knee joint region should then be the site of election. A broad ligature loosely tied was the best.

In the discussion Dr. L. W. Steinbuech said he thought that it had been an accepted method among surgeons not to use the tourniquet in cases of atheroma. While agreeing, therefore, with Dr. Willard, it seemed novel that he should call attention to it. He had used the broad band of the Esnarch apparatus in amputations of the leg for gangrene. In a recent case he had had considerable difficulty in finding contracted vessels, but the patient had made a good recovery. In one case he had not even used the precaution of employing the Esnarch and had had the vessels compressed by the fingers of an assistant, and the patient had recovered.

Dr. Willard said that the point which he had intended to accentuate was that an amputation could be done through the knee joint without loss of blood, even though no constricting band was used.

The New York Academy of Medicine.—At the last general meeting, on Thursday evening, the 18th inst., a paper entitled Further Improvements in Micro-scopical Technique, to be illustrated with apparatus and lantern slides, was to be read by Dr. Henry G. Pfiffard.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 24th inst., a paper entitled Myosis of the Pharynx will be read by Dr. Jonathan Wright, of Brooklyn. Cases will be presented and instruments and apparatus exhibited.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 25th inst., Dr. Grace Peckham-Murray will read a paper entitled Twin Pregnancy with Blighted Fetus, illustrated by a case, and Dr. Edward P. Davis, of Philadelphia, will read a paper the subject of which is to be announced. Cases will be reported and specimens and instruments exhibited.
Original Communications.

Notes on the Preparation of Diphtheria Antitoxine. *

By Charles B. Fitzpatrick, M. D.,
Assistant Bacteriologist, New York Health Department.

In view of the present importance of diphtheria antitoxine and the somewhat complex character of the process involved in its preparation, I have thought that it would be useful to describe the process as simply as possible, and to illustrate it with results of my own work in this field.

General Statement.—Animals can be artificially infected with the diphtheria bacillus or poisoned with its toxine. This infection and this poisoning can be regulated so as to render the animal very sick, but not fatally so. This is accomplished either by administering a single dose or by beginning with an extremely minute dose and repeating after intervals of rest with gradually increased doses. When these animals have fully recovered, they are found to have acquired a tolerance of a fatal dose of the diphtheria toxine or culture. They have acquired an immunity against diphtheria.

The serum of the blood of these animals which have developed this immunity, when mixed in a given proportion with the toxine of the diphtheria bacillus, renders the toxine harmless. This agent, contained in the serum of the blood of animals rendered artificially immune, is called "antitoxine."

If this serum containing antitoxine is injected into other animals, it protects them against diphtheria. The quantity of the serum required to do this bears a certain definite proportion to the weight of the animal.

Specimens of serum obtained from different animals, which have been more or less sick, possess different protective powers. Some, by the administration of a small dose, effect very rapidly a complete protection; others produce only a partial protection or cure, and require much larger quantities.

It has also been demonstrated that the animal which furnishes the serum must have attained an immunity against many times the fatal dose before its serum acquires much power to protect or cure.

The antitoxic value of a given blood serum can be closely determined by finding the weight of a guinea-pig which is protected by a certain quantity of the serum against a deadly infection with the pure culture of the diphtheria bacillus or a fatal poisoning with its toxine. This value is indicated by the proportion between a cubic centimetre of the antitoxic serum and the weight of the test animal protected, estimated in grammes.

Detailed Statement.—The details of the preparation of diphtheria antitoxine are conveniently grouped as follows:

I. The cultivation of the bacillus and the production of the toxine.

(a) Choice of animals employed as tests for the pure culture and the toxine. Principles and ends of the test.
(b) Cultivation of the diphtheria bacilli.
(c) Production of the toxine.
II. The process of immunization.
(a) Choice of animals for immunization.
(b) Remarks upon immunization.
III. The drawing and preservation of the antitoxine serum.
IV. Methods of testing the antitoxine serum.
V. Methods of hastening the immunization.
VI. Accidents during the process of immunization.

I. The cultivation of the bacillus and the production of the toxine.

(a) Choice of Animals Employed as Tests for the Pure Culture. Principles and Ends of the Tests.—For these tests the guinea-pig has been usually employed. It gives the most delicate, exact, and constant reactions. The rabbit may also be used. Young dogs and cats are quite sensitive to the poison and can also be used as test animals.

The mode of using the animals to test the virulence of the cultures and toxines is to inject subcutaneously different amounts of each until that quantity is found which kills the animal within about forty-eight hours.

The animal is prepared for injection by clipping the hair short at the selected places and washing the exposed surfaces with a five per cent. solution of carbolic acid. The place generally employed is the subcutaneous tissue covering the lateral abdominal muscles.

In determining these tests the weight of the animal plays an important part. In testing the different amounts of the toxine and culture which are necessary to kill, animals having the same weight must be employed. Small, young animals are much more sensitive and more easily killed than the larger and older ones.

Behring (1) recommends the use of animals weighing from two hundred to three hundred and fifty grammes, and Roux (2) prefers those weighing five hundred grammes. The exact fulfillment of these conditions is often very difficult. After all, the tests are comparative and upon a varying subject. When this comparison is obtained and the variations are controlled, the desired end is obtained.

I have for purposes of these experiments grouped the animals according to two standards of weight: those which weigh two hundred and fifty grammes, or within seventy-five grammes of this, and those which weigh five hundred grammes, or within seventy-five grammes of it. That is to say, animals within these limits are considered, respectively, two hundred and fifty and five hundred grammes.

* Most of this work was done in the Department of Pathology of the College of Physicians and Surgeons, Columbia College, New York city.
† The material at my disposal has been nineteen horses, together with some goats, dogs, sheep, and one cow, which have been advanced to various degrees of immunity.
‡ Antitoxine is also present in man after he has recovered from diphtheria.
Naturally, any slight deviation from these conditions may also be allowed if properly controlled. For convenience, the first-named guinea-pigs are designated *medium sized,* the others *full sized.*

(b) The Culture of the Diphtheria Bacilli.—The culture of the diphtheria bacillus should be recent and virulent. It can be kept at a given virulence, or within slight variations from this, for an indefinite period by inoculation and reinoculation every forty-eight hours. Upon serum, inoculated every fourteen days suffice. The culture employed in these investigations was occasionally passed through a guinea-pig to maintain and freshen its virulence.

The virulence of the cultures bears an important relation to the production of efficient toxin. The culture most generally employed had such a virulence that the injection of 0·1 c. c. killed a guinea-pig of three hundred grammes in forty-eight hours.

In order to permit of greater facility in describing the following experiments, this culture is called a "standard culture." Cultures requiring 0·2 c. c. and 0·3 c. c. to produce the effect of 0·1 c. c. of a standard culture have been likewise employed. The standard cultures produced toxines of which 0·1 c. c. sufficed to kill a three-hundred-gramme guinea-pig in forty-eight hours. This toxin is for convenience called "standard toxin."

The cultures of which 0·2 c. c. and 0·3 c. c. were required to equal the virulence of 0·1 c. c. of a standard culture also produced standard toxine, but not so constantly as the standard culture. Cultures requiring 0·4 c. c., 0·5 c. c., 0·6 c. c., 0·7 c. c., and 0·8 c. c. to produce the virulent action of a standard culture have also been employed. They produced weak toxines, of which 0·33 c. c. or more were required to kill a guinea-pig of two hundred grammes in forty-eight hours.

Methods of Determining the Virulence.—Roux and Yersin (3) obtained a pure culture by rubbing the exudation from a diphtheritic throat over the surface of a series of serum tubes. The last two generally contain isolated colonies. From these colonies a bouillon culture is made, which is allowed to remain in the incubator at 35° C. for twenty-four hours. One cubic centimetre of this culture is then injected subcutaneously. Behring (4) employs the same procedure, except that he allows the culture to remain for forty-eight hours at 37°.

The injection of this one cubic centimetre is usually sufficient to demonstrate whether the culture is virulent or not. This being determined, it is desirable to find out the exact virulence, or, in other words, the exact dose necessary to kill a medium-sized guinea-pig in forty-eight hours. This is accomplished by beginning with the one cubic centimetre, as above, which generally kills within this period. Then 0·8 c. c., 0·6 c. c., 0·4 c. c., 0·2 c. c., 0·1 c. c., and so further, are respectively injected until that amount is ascertained which just suffices to kill the guinea-pig in forty-eight hours.

The following table, showing one series of tests, illustrates the relation between the virulence and the quantity of the dose:

<table>
<thead>
<tr>
<th>Weight of guinea-pig</th>
<th>Amount of culture injected</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>213 grammes.</td>
<td>0·8 c. c. of a 48-hour bouillon culture.</td>
<td>Died in 48 hours.</td>
</tr>
<tr>
<td>305</td>
<td>0·1 c. c. of same.</td>
<td>Died in 8 days.</td>
</tr>
<tr>
<td>340</td>
<td>0·3 c. c. of same.</td>
<td>Died in 11 days.</td>
</tr>
<tr>
<td>350</td>
<td>0·2 c. c. of same.</td>
<td>Died in 28 days.</td>
</tr>
<tr>
<td>377</td>
<td>0·1 c. c. of same.</td>
<td>Slight local swelling, which disappeared; animal appears normal.</td>
</tr>
</tbody>
</table>

This shows that the culture had a moderate virulence.

If, in making these or similar tests, the culture is such that a very small dose is required, such as 0·1 c. c. or smaller, it can be diluted to advantage with sterilized water. Behring employs this as routine practice, but it is not always necessary.

The Virulence of the Cultures can be Increased.—Roux and Yersin (3) mixed half a cubic centimetre of a bouillon culture of the *Bacillus diphtheria* with the same amount of a culture of the streptococcus of erysipelas. This is injected, and after death pure cultures are made. Aronson (5) removes, after the death of the animal from an injection of a pure culture, a small particle from the hemorrhagic edematous tissue which surrounds the place of injection, and draws this particle over the surface of a series of serum tubes. From these a pure culture is obtained.

The second of these methods produces the better results. By one passage with the latter method a virulence threefold the original was obtained. Aronson (5) claims to have obtained in this way cultures, of which 0·008 to 0·009 c. c. killed a medium-sized guinea-pig within four days. Of this same culture, 0·1 c. c. was required to produce the same effect before having been passed through guinea-pigs.

Having obtained a virulent culture of the diphtheria bacillus, the next procedure is

(c) The Production of the Toxine.—The culture media employed for toxine production have been one-per-cent. and two-per-cent. bouillon. Two per cent. appears to produce toxine more quickly than the one per cent., although there is no practical difference in the strength when produced. The two per cent., in my experience, often produces standard toxine in sixteen days, while the one per cent. usually requires about three weeks. Bouillon, to which one per cent. of glucose had been added, yielded after three weeks' incubation toxines of which 0·2 c. c. were necessary to kill a medium-sized guinea-pig in forty-eight hours. Five per cent. of glycerin added to the bouillon produced a toxine of which 0·33 c. c. was required to equal the action of 0·1 c. c. of standard toxine.

The reaction of the culture media must be distinctly alkaline. Neutral or slightly acid media do not favor good growths. The reaction which was found best is one which gives a faint alkaline reaction with litmus paper. With phenolphthalein solution (one per cent., in fifty per cent. alcohol) it is distinctly rose without being markedly so.

The shape of the containing vessel in which the culture is made for the production of toxine which has given, as a rule, the best toxine, has been that of the ordinary half-litre flasks. These were half filled with bouillon. Vessels
which were made according to Fernbach (6) have produced no better results. Fernbach's flasks are flat-bottomed, with a straight neck and a lateral tubulature in one side, about four centimetres from the base. They are filled to just below the tubulature.

Roux and Yersin's method of growing cultures in a current of moist air, which enters the neck of a Fernbach flask and escapes through the tubulature, have produced good toxines, but, so far as our experience extends, no more quickly and of no greater strength than by the use of simple flasks.

Aronson's method of growing cultures in a current of oxygen have given uncertain results, and we wish to have further experience before expressing a positive opinion.

The exact amount of bouillon to put in each vessel to attain the best production of toxines is yet to be determined. We have employed as much as a litre in two-litre flasks, and also the same amount in Fernbach vessels, with good results.

The inoculations of the media have been effected by means of a minute drop upon the platinum wire. Roux (7) inoculates the media with twenty-five to fifty cubic centimetres of a culture which has grown in the incubator for from twenty-four to forty-eight hours. This is a good procedure, as it insures a good starting of the growth. We have found five to ten cubic centimetres of a like culture to answer this purpose.

After being about three weeks to four weeks in the incubator at 37°C, a small portion of the bouillon is removed by means of a pipette and tested.

The cultures may be allowed to stand at room temperature after removing them from the incubator, for some weeks, without deterioration in the toxine formed. It may be allowed to remain in the incubator during the process of testing (i.e., about three to five days) without causing any practical change.

If the toxine be found to be standard toxine or approximating this, it is removed from the incubator. If not, the culture may still be allowed to grow for about six weeks. Toxine weaker than 0.33 c. c. fatal to a medium-sized guinea-pig in forty-eight hours, I do not generally use, because, as immunization proceeds, the dose becomes too large for convenience. But toxine even weaker than 0.33 c. c. gives toxine reactions, and consequently can be used if needed.

The method of testing the toxine is essentially the same as that described for testing the pure cultures. The object to ascertain is the exact amount which can kill a medium-sized guinea-pig in forty-eight hours. The following table shows such a series of tests and their results:

<table>
<thead>
<tr>
<th>Weight of guinea-pig</th>
<th>Amount used to inoculate</th>
<th>Result.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Medium-sized</td>
<td>0.33 of a two-per-cent. peptone-bouillon culture, grown 16 days at 37°C.</td>
<td>Died in less than 18 hours.</td>
</tr>
<tr>
<td>259 grammes, 249 g.</td>
<td>0.2 c. c. of same.</td>
<td>Died in 48 hours.</td>
</tr>
<tr>
<td></td>
<td>0.1 c. c. of same.</td>
<td>Died in 48 hours.</td>
</tr>
</tbody>
</table>

This toxine is that which I have designated as "standard toxine."

Preparation of Tested Toxines for Use.—By passing the bouillon culture containing the toxine through two or three layers of sterilized filter paper, a clear filtrate can be obtained. This is not entirely free from the bacilli, but is clear and easily diffusible in the tissues.

The bouillon culture containing the toxine can also be filtered through porcelain filters and made perfectly clear and free from bacilli. The form of the porcelain filter with which I have succeeded the best is Muencke's large cylinder and glass receptacle. Kitasato's filter has also been employed, but is not so well adapted or as convenient as the above for filtering large quantities. A simple arrangement for filtering consists in supporting a moderately sized glass funnel above an éprouvette with a high lateral tubulature containing a Pasteur-Chamberland bougie. The outlet of the funnel is connected by a rubber tube with the bougie, and the tubulature with an ordinary water aspirator, which can also be used for the preceding two filters.

Behring's method of simply decanting the clear portion and adding 0.5 per cent. of carbofolic acid has also been employed. The carbolic acid kills the remaining bacilli and does not interfere to any practical extent with the activity of the toxine. The objections to this method of decanting are that small particles are apt to remain in the fluid and may block the needle; furthermore, the dead bacilli remaining in the decanted fluid, when injected, may act as an irritant and cause abscesses.

Every culture does not produce good active toxine, even if all the conditions apparently necessary have been fulfilled. Two cultures from the same source grown under exactly the same conditions often produce toxines differing widely in strength. O. Boer, who worked with Behring, mentions having upon one occasion obtained only five litres of strong diphtheria toxine from some hundreds of litres grown under like conditions. With standard cultures, and with some which were slightly more virulent, grown under favorable conditions, I have obtained to date about one litre of standard toxine for every eight litres grown.

In making fresh inoculations from old bouillon cultures, it is best to secure the bacilli from the surface of the media, as they are younger and more virulent than those found in the deeper layers.

Aronson (8) maintains that, by causing a whitish-gray pellicle of the bacilli to grow upon the surface of the bouillon, he has found a method by which he has constantly produced very strong toxine. My experience does not agree with his. The toxine production appears to depend upon the virulence of the culture, which should preferably be inoculated and grown at first upon the surface of the bouillon. Whether this forms a pellicle or not seems to me a matter of indifference.

Toxine is preserved by the addition of 0.5 per cent. of carbofolic acid and should be kept in a cool and dark place in a well-filled air-tight flask. Toxine which has been filtered through porcelain maintains its strength for a long time (from my experience, three months) without the addition of carbofolic acid.
11. THE PROCESS OF IMMUNIZATION.

(a) Choice of Animals for Immunization.—Those most commonly employed are the horse, sheep, goat, dog, and cow.

It is not true, as Behring (9) originally taught, that the animal possessing the greatest sensitiveness to the poison produced the best antitoxin.

The horse, which was formerly believed to be refractory to diphtheria, has been proved by Roux (2) and Martin to be the best adapted for producing antitoxin. It bears the loss of large quantities of blood with no evil effects and can be easily and quickly immunized.

The normal temperature of the horse is 100° F. Practically 99° to 101° F. is considered normal.

After the injection of the toxine or culture there is a period of reaction which is generally characterized by a rise of temperature. Weakness, loss of appetite, ataxic gait, or even complete prostration and death may also occur.

The horses which have proved themselves the best adapted to bearing the process of immunization are ordinary working horses accustomed to hardship. Mustangs have a very good tolerance of the poison and as a breed are among the best to use. Finely bred and carefully nurtured horses appear to be more sensitive than others, and are apt to react with abnormally high temperatures and long periods of illness. We have selected horses weighing from about a thousand to twelve hundred and fifty pounds as the best size to handle. The horse must be healthy, especially having no kidney lesions or any disease of the internal organs.

Healthy horses with old bone lesions of the feet can be very well employed. The horses are carefully examined for glands. In my horses no case of glands has been found. The injection of mallein caused only slight reactions.

In one case a reaction, indicated by a rise of temperature of four degrees and three fifths Fahrenheit, was caused, with swelling and no prostration. After an interval of rest this horse was again injected and gave no reaction.

The time to inject mallein is preferably before starting the diphtheria injections. It may also be employed during the course of the immunization, provided it is not used within the period of reaction.

The presence of tuberculosis should also be guarded against by the use of tuberculin.

The cow can be quite readily immunized, and the milk is found to contain antitoxine. It is difficult to obtain antitoxine of a high activity in a cow. The dog and sheep react moderately and are readily immunized. The goat, however, is extremely sensitive, requires much attention, and, as a whole, does not give good results. It reacts with long periods of increased sensitiveness and often develops a cachexia.

For the sheep and goat I have adopted Behring's (9) plan of considering everything under 104° F. as normal. The dog's normal temperature is about 101.5° F. and may vary about one degree without special significance.

(b) Remarks upon Immunization.—The process of immunization begins with the subcutaneous injection of so small a dose of the pure culture or toxine of diphtheria that it is readily tolerated. This dose is gradually increased, after intervals of rest, until many times a fatal dose can be borne.

During the period of reaction the animals exhibit an increased susceptibility to the diphtheria poison. When this period of reaction is present the administration of a dose equal to the last administered can very well cause death or so serious an illness as to interrupt treatment. One must wait before administering another injection until the temperature and general state of the animal have returned to normal.

During the last stages of immunization the doses can be increased much more rapidly than at the beginning.

The pure culture or the toxine can be used for the purpose of immunizing. Toxines of a known strength and free from bacilli are the most convenient and exact. The reaction is undoubtedly in both cases due to the toxine. The culture produces its reaction by means of the toxine it contains at the time of injection and that formed after injection. Its action is consequently more gradual and less concentrated than that of the toxine. The culture, so far as my experience goes, appears just as well adapted as the toxine for causing the ordinary reactions of the treatment.

When, as occurs toward the end of the immunization, a very strong impression is needed to produce antitoxine of a high activity, the toxine, or a mixture of the toxine and culture, are indicated.

There is no doubt that the toxine, plus the dead bacilli, effect more reaction than the toxine alone. But this reaction is due in part to the irritation caused by the dead bacilli, and is not the desired toxine reaction. If an increased reaction is desired, it is much better to mix the toxine with a pure living culture. This causes much less irritation and produces the desired toxine reaction.

A considerable portion of my toxine has been filtered and compared in its action with the unfiltered. It was found to cause decidedly less swelling than the unfiltered and gave as good reactions. With it the period of reaction appeared shorter and more clearly defined. Inasmuch as it is extremely desirable to eliminate all elements of uncertainty, and especially such as hide the real toxine action, the use of a filtered toxine becomes a matter of considerable importance.

There is a great difference of tolerance in individual horses. In some, two cubic centimetres or even five cubic centimetres of a standard toxine or culture can be used with impunity as the initial dose and rapidly increased. In others, a much smaller dose gives a marked reaction and must be diminished or combined with a two per-cent. solution of the trichloride of iodine (9) of from one to three times its volume, or with five to ten (2) times its volume of Gram's solution, both of which diminish the effect of the poison.

The safe routine initial dose is half a cubic centimetre of a standard toxine or culture. Notwithstanding these precautions there are horses which react disproportionately, and after every increase in dosage become very ill with long periods of reaction.
The average time required to immunize a horse is from two and a half to three months and a half. A reasonable limit of time to be devoted to the immunization of a horse I believe to be six months.

A supersensitive horse can be made to yield good active serum. Behring (1) has some animals which respond strongly to one one-thousandth of an ordinary dose, and yet at the same time yield a serum with a very high antitoxic power.

The usual places of injection are in front and behind the shoulder, the chest, and the lower anterior cervical region; but any place may be selected where the skin and subcutaneous cellular tissue are sufficiently loose and abundant to admit of some swelling. The skin over the places chosen for injection should be closely clipped and washed with soap, alcohol, and bichloride or carbolic-acid solution.

The needle to be employed must be strong. Horses have a way of twitching the superficial tissues, especially in the region of the shoulder, in such a way as to break the ordinary hypodermic needle when introduced into the subcutaneous tissue.

The syringe employed is the ordinary hypodermic syringe. Two sizes have been used, one having a capacity of eight cubic centimetres, the other a capacity of about fifty cubic centimetres. Martin (10) suggests the attachment of the needle to the syringe by a small piece of rubber tubing ten centimetres in length. This admits of movement without disturbing the relations of the introduced needle.

The amount injected subcutaneously in one place should not ordinarily exceed fifty cubic centimetres. In the horse one hundred cubic centimetres can be so injected by using a needle ten centimetres long and by changing its direction as the syringe is gradually emptied.

The formation of local necroses after injections of the pure culture or toxine occurs in some animals as a regular reaction. In the horse toxine does not cause necrosis, but with the pure culture a necrosis sometimes occurs, especially if the injection is superficial. In the goat and sheep I have not seen or caused anything more than a diffuse hard swelling. Guinea pigs give necroses with both the culture and the toxine.

In many horses undergoing immunization a swelling arises upon the middle of the abdomen. It is an oblong, pear shaped tumor, about the size of a hand. It is subcutaneous, easily movable, and has no apparent connection with any of the other swellings which may be present. It occurs at a variable period, usually seven or twenty-five days after the commencement of the treatment. It seems to have had no effect upon the progress of the immunization.

A careful observation of the temperature and weight of the animals undergoing immunization is important. Loss of weight is the best indication of the beginning of a cachexia, sometimes caused by the process of immunization. Weight taken once a week answers all practical purposes.

The temperature usually rises after each injection of the toxine or culture, and then usually returns to normal in from two to four days. The height of the temperature is a fair measure of the severity of the infection or poisoning. It is important during the immunization to take the temperature twice a day, as, especially in horses, marked changes may occur between morning and evening temperature.

The temperature of the horse after an injection with the toxine or culture of diphtheria—
1. May remain normal.
2. May rise one or two degrees, and in one to three days return to normal.
3. May, when the rise of temperature is above two degrees, return to normal or nearly normal by the third or fourth day, and begin on the fourth or fifth day to rise to a slight extent, or as much and sometimes more than directly after the injection.
4. May rise and remain slightly above normal for about ten days, with intermission of one or two days of normal temperature.
5. May be a decided rise and then return to normal gradually, occupying about ten days.
6. May fail to below normal and remain so one or more days without apparent cause soon after a dose approximating the preceding one. When the animal shows no other symptoms of reaction, this is always to be considered an indication that it is safe to administer another and an increased dose.

The characteristic temperature reaction is a decided rise within about twenty-four hours after injection, followed by a fall to normal or nearly so on the third day, and then a second rise varying from being a very slight one to one exceeding the reaction directly following the injection. If the temperature returns to normal and remains there three days, it generally does not rise again. If the temperature due to a reaction be slightly above normal, with normal intermissions, it is generally to be regarded as normal, and as an indication for a fresh injection after a moderate period of rest.

The horses should have plenty of fresh air. Moderate exercise is also indicated.*

Horses which have received a large enough dose to cause a well-marked reaction should not be exercised directly—i.e., within twelve to twenty-four hours—after its administration. Exercise will often cause the temperature to rise one to two degrees, sometimes even when three or four days have elapsed since the last injection.

In the ordinary routine immunization of a horse the objects sought are, in general, to cause reactions of about one to two degrees and to maintain the animal in full weight and health.

Chart No. 1 illustrates this routine method. The beginning dose, to test the sensibility, was one cubic centimetre of a nineteen days' old standard culture. At nineteen days its virulence was about a fifth of that at forty-eight hours. Hence the be-

---

* Guine-pigs demonstrate very strikingly the need of fresh air, sunlight, and exercise. Those which are kept in a large cage, with plenty of air and sun, survive others which are kept confined in darkened places by many hours, sometimes two or three days, when both have been injected with exactly the same deadly dose.
the standard dose was equivalent to 0.02 c.c. of a standard toxine or culture. This caused a reaction of about one degree, thus showing that the animal was probably more than usually sensitive. From this time on the dose was cautiously increased according to indications. Small variations of temperature up to about 101°F. can be disregarded when a moderate length of time has elapsed and the horse appears normal in other respects. An illustration of this is the fifth injection made when the temperature was 101°F. The reaction caused was about one degree.

This horse was more than ordinarily sensitive, and the cultures and toxines could have been mixed to advantage at the beginning with the trichloride of iodine or Gram’s solution, as already mentioned.

The treatment on the whole was conservative, the full time for each reaction being observed and no reaction of more than two degrees and three fifths (Fahrenheit) was caused until late in the treatment. The horse, after four months of treatment, was in the best of health and gave antitoxine of 1 to 200,000 according to Roux.

After the process of immunization has been advanced sufficiently to produce antitoxine of the required strength, this degree of immunity must be maintained by further injections.

The injection once in twenty days of one large dose (two hundred to four hundred cubic centimetres) of standard toxine into the jugular preserves the immunity and is very convenient. As much as six hundred cubic centimetres of a toxine of which 0.1 c.c. killed a five-hundred gramme guinea-pig has been injected at one time into the jugular of the horse without causing death (2).

Another method of maintaining the immunity is to inject subcutaneously ten to twenty cubic centimetres of standard toxine every two or three days, provided it causes no grave symptoms.

The method which we have adopted as the best for maintaining the immunity consists in injecting subcutaneously, when the period of reaction and a moderate interval of rest (three to six days) have elapsed, an amount of toxine equal to the last injection. If it is desired to increase the immunity still further, one must proceed according to the principles.
already mentioned. After a tolerance of one hundred to two hundred cubic centimetres of standard toxine has been established, frequent increases of one hundred cubic centimetres, and even sometimes two hundred cubic centimetres, can be made without risk. Doses can be increased up to about seven hundred and fifty cubic centimetres subcutaneously of a toxine or culture of which 0·1 c.c. kills a five-hundred-gramme guinea-pig in forty-eight hours.

To increase the degree of immunity, frequent injection of moderately large doses (cere two hundred cubic centimetres) appears to be better and less dangerous than the administration of one large dose of six hundred cubic centimetres or more at long intervals.

III. THE DRAWING AND PRESERVATION OF THE ANTITOXINE SERUM.

After the animal has been subjected to the immunizing process sufficiently long to have acquired a good tolerance of the toxine or culture, it is proper to withdraw some of its blood to test.

The period of time and the dosage necessary to develop antitoxine vary greatly. A sheep which had undergone the process of immunization for sixty-three days, and which had reached a tolerance of a dose of twenty cubic centimetres of a toxine one third as strong as standard toxine, yielded strong antitoxine.

In the horse, it is usual to wait before testing until a dose of one hundred cubic centimetres standard toxine is tolerated; twenty-five cubic centimetres of blood will furnish enough serum for testing the antitoxine value of the blood.

For some days after the injection the blood may be toxic (11). As a rule, it is best, when a moderately large injection has been employed, to draw the blood in from eight to twenty days after the last toxine or culture injection. After a small injection with rapid disappearance of reaction, one need not wait so long, but may bleed in about five days after the injection.

From six to eight litres can be drawn from the horse at one time, and the bleeding can be repeated every three weeks.

Sheep bear the withdrawal of two hundred and fifty to five hundred cubic centimetres very well. Behring and Boer (12) repeated this in one case, with no evil results, every fourteen days. We have found an interval of rest of three weeks to be indicated.

In an endeavor to find some rule as to the quantity to be drawn in different animals, I have come to draw half a litre for every hundred pounds of the animal's weight, and have found this rule applies to about every case.

The method of drawing the blood is to insert a trocar into the jugular. The trocar employed, which was devised by me, is a simple cannulated one, ten centimetres in length and four millimetres and a half in width. It should be moderately sharp for two millimetres from the point, and the rest of the edge of the point should be blunt. A cannulated trocar has the great practical value over a solid one, inasmuch as the moment the vein is entered the blood begins to flow.

To the end of the cannula is attached a piece of rubber tubing thirty-eight centimetres in length, and this is in turn attached to a piece of bent glass tubing, twenty-three centimetres in length. This tubing, etc., are sterilized by heat and kept in five-per-cent. carbolie solution. This is, according to our experience, the simplest and best adapted apparatus for bleeding.

Instead of connecting the cannula with rubber tubing, a cannulated pia (Roux) can be used to connect the cannula with the rubber tubing, and which is to be joined to the cannula after the flow of blood has begun.

If the metallic trocar is not to be had, a glass tube of like size, bent at an oblique angle, with one end drawn out and filed off obliquely, can be used. The rough edge is made smooth by heating in the flame.

The Method of Insertion of the Cannula into the Vein.—

The skin is first prepared by clipping the hair and washing with soap and applying alcohol and carbolie-acid solution. Then incise the skin two centimetres and a half in length directly in the line of the jugular. This exposes a white, thick fascia which must also be incised.

An assistant stands directly in front of the horse, and with his thumb compresses the jugular at about ten centimetres below the incision. The operator or, better, an assistant then compresses the vein about two and a half to five centimetres above the incision. The vein is now taken firmly by the operator between the thumb and forefinger of one hand, while with the other hand the trocar is inserted upward, at slightly less than a right angle with the skin surface, directly into the vein.

The trocar should be slowly but firmly introduced, the hand carrying it being supported against the neck of the horse. The end surface, making up the point of the cannula, should be kept undermost. After the blood begins to flow, the point of the trocar should be turned somewhat more upward and pushed into the vessel for about two centimetres and a half, and its free end held at the proper angle in one hand, which is supported against the neck of the horse. If the horse struggles, this hand should be pressed firmly against the neck, as in this way the movements of the horse can be followed without disturbing the position of the cannula.

If the horse is to be bled to death it is advisable to have him tied down and to use a cannula five millimetres and a half in diameter. The horse often struggles violently before dying.

After withdrawing the trocar, the skin should be united by sutures or a pin-suture.

Wide-mouthed vessels of a capacity of about five hundred to seven hundred cubic centimetres are ordinarily the best-adapted for collecting the blood.

Erlenmeyer flasks of this capacity also answer this purpose. With ordinary balloon flasks so much movement

* With the glass cannula it is better to cut directly down upon the jugular and expose it. It should be brought forward upon a curved director and a small oblique incision made, through which to insert the glass cannula. Two loose ligatures are also useful, one above and one below the incision in the vessel. This gives perfect control and enables one to recover the vein again if the cannula becomes free.
FITZPATRICK: PREPARATION OF DIPHTHERIA ANTITOXINE. [N. Y. Med. Jour., 520

is usually required to remove the lower portion of the serum, that the serum is apt to become quite bloody. Erlenmeyer flasks with a low side neck combine a good collecting vessel with the advantage that the serum can be gradually decanted through the side neck without exposure to the air.

The vessels should be a little more than half filled. The mouths of the receiving vessels are covered by two filter papers which have been pressed firmly down and around the mouth, so as to form a loose-fitting cap. The under one is attached firmly, either by pasting or by a rubber band, and the upper is allowed to remain loose. The whole is sterilized. If dry heat is used, the rubber band must obviously be attached later.

The glass tube is plunged through the under cap after removing the upper, and the vessel about one half filled, the tube removed, and the upper cap put in place. These paper coverings are very convenient. Their employment originated in the Pasteur Institute, Paris.

After removal, the blood should be put in a cool place and allowed to clot. Usually it is allowed to stand in the icebox for twenty-four to forty-eight hours. If the clot becomes adherent, it should be loosened in about two hours after the withdrawal. About one third of the blood separates as serum.

The Pasteur balloon pipette, the ordinary pipette, or a siphon pipette may be used to draw the serum off. It is convenient to collect such as appears perfectly clear in one set of vessels, and to put the cloudy or bloody in others to settle.

The preservatives are chloroform, camphor, and carbolic acid; 0.5 per cent. of carbolic acid has been found sufficient to preserve the serum. It is the best preservative, but, owing to its poisonous qualities, it can only be used when the amount of antitoxine serum to be used at one dose is small. For this reason, Behring has made it a rule never to use an antitoxine serum of which more than about ten cubic centimetres are required at one dose. The carbolic acid added should be a five-per-cent. watery solution.

Serum preserved by carbolic acid develops after some weeks an albuminoid precipitation, which can readily be removed by filtration. Behring (13) recommends allowing the serum to stand for fourteen days, after the addition of the carbolic acid, in order to obtain a complete precipitation of the albuminoid substances caused by the carbolic acid, and to allow the serum to mature. There is a slight decrease in the strength of the antitoxine due to the action of the carbolic acid. An old serum, he maintains, is much less likely to cause irritation, skin eruptions, etc., than a fresh one, because the irritating substances which are present in the serum are gradually made harmless by the carbolic acid without affecting the strength of the antitoxine.

Camphor is the best thing to use when large doses are necessary. A small piece, about one cubic centimetre, is used to each twenty five to forty cubic centimetres. It is added to the serum after being passed through the flame. Camphor rarely causes a deposit and no loss of strength has been noted. It is more a preservative than an antiseptic.

Behring (9) recommends chloroform, to the extent of 0.5 per cent., as the best preservative after carbolic acid. Chloroform causes occasionally a slight deposit.

We have also employed chloroform and camphor together and obtained good results.

The final step is to put the required amounts for dosage in small bottles, preferably of colored glass, for distribution. A rubber or closely fitting glass stopper, firmly tied on, is the best means of keeping the bottles properly closed. Cork may also be used.

The serum 1 obtained upon Christmas, and preserved according to the different methods mentioned, has maintained its strength fourteen weeks unimpaired.

During all the manipulations the strictest asepsis should be observed. Much handling and exposure often cause contamination even when carbolic acid has been used (9). If it is desired to simply preserve the serum, it should be put in medium-sized flasks, which are well filled, kept at a cool, constant temperature, and well protected from the light. A temperature of 70° C. destroys the activity of the antitoxine. It is preserved the best in the ice-box.

If the serum is not clear it can be filtered. In addition to the filters already described for filtering toxins, sterilized absorbent cotton has also been employed with good results. Considerable pressure is necessary if a porcelain filter is used. This pressure is best obtained by the use of an air pump to cause direct compression of the air over the serum. Strong aspiration can also accomplish the same result.

Filtration through porcelain is also a very good procedure to preserve the serum and free it from previous contamination. Aronson and Roux employ it as routine practice.

The antitoxine serum is transparent and usually of a straw color. It may vary from a light straw color to a bright red.

Serum containing considerable of the coloring matter of the blood is said by Behring (9) to leave a discoloration in and under the skin if injected subcutaneously. From a clear settled serum of an intense red color injected subcutaneously no discoloration has been observed.

Behring (11) believes that the antitoxine would maintain its strength for a year without change, or, if any, so little as not to influence the usefulness of the antitoxine serum.

IV. METHODS OF TESTING THE ANTITOXINE SERUM.

Antitoxine serum is tested either—

(a) By mixing it with toxine and injecting the mixture; or

(b) By the injection of the antitoxine serum, followed at a variable length of time by the administration of the pure culture.

(a) Tested by Mixing with Toxine.—If diphteria toxine and antitoxine serum are mixed together (14) in a certain proportion, the antitoxine renders the toxine harmless. The proportion required to show this action of the antitoxine has been subjected by Ehrlich (15) to careful research, and he has found that it forms a very reliable basis for testing the strength of the antitoxine.
One cubic centimetre of normal toxine* is mixed with varying amounts of the antitoxine until the exact amount is ascertained which renders the toxine harmless, when both are injected together in the test animal.

If 0.1 c.c. of the antitoxine serum renders one cubic centimetre of the normal toxine harmless, it is designated as "normal antitoxine serum."

In order to ascertain if the toxine has rendered the toxine harmless, the mixture must be injected subcutaneously into a guinea-pig weighing from two hundred to three hundred grammes. If death, loss of weight, or local infiltration, with swelling and induration, result, the toxine is still poisonous. If none of these symptoms occur, and the animal remains perfectly well, the toxine has been rendered harmless.

If 0.05 c.c. of normal antitoxine serum (i.e., a fifth less than when no reaction results) is mixed with the one cubic centimetre of normal toxine, a local infiltration and loss of weight are caused. If 0.2 c.c. of antitoxine is necessary to render the one cubic centimetre of normal toxine harmless, it is half normal serum, and so further. If, on the other hand, only 0.05 c.c. of the antitoxine is required to accomplish the same result, it is twice normal serum. If it needs only 0.025 c.c., it is four times normal serum. This series, one way or the other, is carried further, until the exact amount is found which renders one cubic centimetre of normal toxine harmless.

Instead of one cubic centimetre of normal toxine, we have also employed in these tests three cubic centimetres of a toxine a third as strong as normal toxine, with like results. Strong antitoxine is often sixty to one hundred and fifty times normal antitoxine serum.

One cubic centimetre of normal antitoxine serum is designated as an "antitoxine unit." A cubic centimetre of strong antitoxine sixty to one hundred and fifty times normal antitoxine, would consequently contain sixty to one hundred and fifty antitoxine units.

**Experiments of mixing Serum and Toxine to Test the Strength of the Antitoxine. December 25th, 9 P.M.**

Blood of horse, Chart II: drawn December 25th,

These tests show the serum to be at least four times as strong as normal serum.

In this series one six-hundredth of a cubic centimetre was mixed with one cubic centimetre of the toxine, and the animal still survived. This shows that this antitoxine serum is sixty times as strong as normal antitoxine, or that one cubic centimetre contains sixty antitoxine units.

(b) **Antitoxine Tested by the Injection of Antitoxine fol-**
of grammes of the guinea-pig which are protected by a given quantity of the antitoxine serum. If, for example, a five-hundred-gramme guinea-pig receives an injection of 0.002 c.c., it has received one one-hundred-thousandth of its weight, and if this amount protects it against a deadly infection with the pure culture, it shows, the above proportion being reduced to whole numbers, that one cubic centimetre of the antitoxine serum has protected one one-hundred thousand grammes of guinea-pig, and is expressed by saying the serum has a protective power of one to one hundred thousand.

Behring (16) employs ten times the minimal fatal dose from a quarter to four hours after the injection of the antitoxine. Normal serum so tested has an activity of about one to five thousand. Roux (1) injects the antitoxine twelve hours before a dose of the pure culture, which kills in less than thirty hours.

The exact minimal fatal dose is not employed for these tests, because a dose sufficient to kill within about forty-eight hours is required in practical work, and the minimal dose kills in from three, four, or five days to some weeks. If the antitoxine is to be tested by separate injections at different intervals, opposite sides of the animal are used when this interval is from a quarter of an hour to four hours. The side is optional when the interval is twelve hours or more.

The following table is selected from a set of experiments by this method, according to Roux, who is now generally followed in making these tests:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

In this test the animals which are considered protected must be free from local oedema, necrosis, etc. In the above tests one one-hundred-thousandth protected sufficiently to prolong life in one case twenty-nine days and in another fourteen days, preceded by local swelling and necrosis.

Five times the dose fatal in forty-eight hours is generally certain to cause death in less than thirty hours. If the proportion is maintained these tests may be made with medium-sized or full-grown guinea-pigs. An interval of eighteen hours has been allowed and is not found to differ to any practical extent from when twelve hours intervene.

A Comparison of the Equivalence of the Results obtained by the Methods of Ehrlich and Roux.—An antitoxine serum of one to fifty thousand, according to Roux’s method, is equal to about sixty times normal antitoxine serum. One cubic centimetre of one to fifty thousand consequently contains sixty units.

Upon this basis ten cubic centimetres equal six hundred normal antitoxine units, which is the number contained in bottle No. 1 of the Behring antitoxine. Calculated further, sixteen cubic centimetres and two thirds equal a thousand normal antitoxine units, which are the contents of bottle No. 2 of the Behring antitoxine. And again, twenty-five cubic centimetres equal fifteen hundred normal antitoxine units, which correspond to the number contained in bottle No. 3 of the Behring antitoxine.

v. Methods of hastening the immunization.

One can proceed more rapidly to immunize than by the routine practice already described.

Instead of causing reactions of one and two degrees, reactions up to four and five degrees can be obtained. The interval of rest can also be shortened, and upon the first return to normal, or within one or two days of it, the horse can be again injected. Of course, by pursuing this method a considerable element of risk must be encountered and overcome. Between the strict following of this plan and the routine schedule already laid down, there is a mean for a hastened treatment which can be pursued with little or no risk.

The case shown by chart No. 2 is a striking example of a hastened treatment, the reactions being generally from three to five degrees. The temperature curve of this case illustrates admirably how the organism of the horse accustom itself to the poison. Five cubic centimetres caused at first a temperature of 105° F., then 104° F., and later 101° F.; two hundred cubic centimetres finally not producing as much temperature reaction as five cubic centimetres did at the beginning.

Besides hypodermic injections intrajugular ones were also employed, the object being to get a direct, intimate mixing with the blood and to produce a more decided reaction. The first intrajugular injection caused a rise to 105° F.

The administration of toxine in this manner is about a quarter more fatal than when injected subcutaneously. When an especially strong reaction is desired, as toward the end of a prolonged treatment, in order to get a very highly active serum, it is proper to use intrajugular injections, otherwise they are not indicated for general employment.

The periods of rest were made as short as possible, yet not unreasonably so, as shown by waiting eight days after the first intravenous injection. The strain upon the horse was very severe, as is well illustrated by the loss of a hundred and fifteen pounds within forty-three days. This horse was one of the first horses immunized in New York.

The continued increase of large doses to cause so marked reactions was undertaken from the conviction which had resulted from studying many cases—namely, that the antitoxine does not begin to be formed to a marked extent until a decided and stimulating amount of toxine is used.

The time occupied (fifty-seven days) is the shortest period, so far as I know, in which a horse has been sufficiently immunized to produce antitoxine equal to Behring’s No. 1.

The horse was bled to death on December 25th, in order to obtain as large a supply of serum as possible for immediate use. The amount of blood obtained was twenty-five litres. About fifteen litres, that which was first drawn, came in a constant stream; the rest was gathered directly after death from
the blood which remained in the blood-vessels. Of the first fifteen litres, about a third separated as serum. A much lower proportion of serum was obtained from the other.

In the preceding case the swellings caused in general a diffuse general hardness, with no softening at the periphery and no tendency toward necrosis. The first injection caused a very decided swelling; the whole pectoral muscles were swollen, and the chest protruded about six centimetres.

The swelling caused by extravasation upon November 11th spread along the sheath of the jugular and involved the muscles of the jaw. About eight centimetres below the angle of the jaw, directly in the line of the jugular, a firm tumor formed which contained necrotic tissue and some dark-colored pus.

The presence of an abscess is not ordinarily an indication to stop treatment, unless it causes temperature and general disturbance of the well-being of the horse. In three cases, when large abscesses were present, large injections were made, with no evil results.

VI. ACCIDENTS DURING THE PROCESS OF IMMUNIZATION.

We have had two cases, one in which pneumonia complicated the injection of the poison and resulted in death.

\[\text{Just what relation this pneumatic process bore to the poisoning could not be determined.}\]

In the other, the horse was kicked in the knee joint. This injury appeared to be aggravated by the toxic injections and resulted in a large wound and suppuration and finally involved the joint. The injury caused a temperature of 104.8°F. and stopped the treatment. The horse not regaining the use of the limb, it was deemed advisable to put it to death.

The occurrence of a period of prolonged reaction, which appears to return to normal two or three days after injection, but which rises again and remains high, can very well mislead the most careful. The injection of a dose the same as the preceding dose, or of an apparently properly increased one, during this first return to normal, can cause a serious interruption or even death.

\[\text{Animals Undergoing Treatment are apt to Acquire a Cachexia.—This is most marked and easily caused in the goat. The horse also readily develops a cachexia. This}\]
is made known by loss of weight, appetite, and a tendency for the temperature to remain above normal for an unusually long time after an injection.

The chart No. III illustrates a case in which the temperature would have risen, most probably, after an interval of normal. The goit\(^*\) was unusually sensitive, and was beginning to show signs of a well-marked cachexia, when the final dose caused its death.

A poor tolerance possessed by an individual horse can also very well be the cause of death. The chart No. IV shows this very strikingly.

I wish, before concluding, to express my sense of indebtedness to Professor T. Mitchell Prudden, whose support and advice have made these investigations possible. I am also under many obligations for material and suggestions to Dr. H. M. Biggs and Dr. W. H. Park.

**Contribution to our Knowledge of Concentric Narrowing of the Visual Field.**—Groenouw (Arch. für Ophthalm., xl, 2) gives the following results of his observations: 1. The extension of the concentric narrowing of the visual field, due to functional lesions, depends within certain limits upon the degree of accommodative tension under which the visual field is measured. 2. The paradoxical widening of the visual field can only be clearly demonstrated when the visual field shows a greater concentric narrowing. It may be shown to exist in anesthesia of the retina, k opacity, hysteria, hemicrania, spastic myopia, traumatic neurosis, and tobacco amblyopia. 3. The paradoxical widening of the visual field again disappears in relaxation of the accommodation, and in its place appears the physiological narrowing of the visual field, as soon as the patient can be regarded as completely cured and the visual field has regained its normal extent.

**The Treatment of Typhoid Fever with Typhoid Thymus Extract.**

By Alexander Lambert, M. D.,

Visiting Physician to Bellevue Hospital.

In October, 1893, Eugene Fraenkel \(\dagger\) reported to a medical association in Hamburg his treatment of fifty-seven cases of typhoid fever by the deep subcutaneous injection of thymus boillon in which the typhoid bacillus had been grown and then killed. At the same time Th. Rumpf \(\dagger\) reported thirty cases treated by the dead cultures of the *Bacillus pyocyaneus* grown and prepared in the same manner as the typhoid cultures. These authors state that half a cubic centimetre of these cultures injected deep into the gluteal region, followed by the injection of one cubic centimetre twenty-fours later, is, as a rule, followed by a slight rise of temperature, with or without a chill; on the third day a decided fall of temperature, not to be accounted for by the ordinary course of the disease, and on the following day a fall still more marked. If the temperature rose again, under a continuance of the injections in increasing dosage at forty-eight-hour intervals, the patient in from six to eight days would be apyretic. The pulse comes down to normal with the fall of temperature. No untoward symptoms appeared referable to the heart's action, nor to the lungs or kidneys. When a chill accompanied the rise after the injections the heart's action did not increase correspondingly with the rise of temperature. Even when the full of temperature was not complete, the fever changed from the continuous to the remittent type. Still more marked was the change in the general condition of the patient under the influence of the injections. The somnolence, stupor, and delirium disappeared; sleep became natural; the coated tongue cleaned; the diarrhoea disappeared, and the meteorism improved. The patients' appetite returned, and they complained of hunger, even though the successive crops of roseola continued and the spleen only slowly diminished in size. There was often profuse sweating and marked diuresis.

This treatment, however, did not prevent complications nor relapses, but when the latter did occur they quickly yielded to further injections. In some cases, however, this treatment was without effect. Moreover, the earlier the stage of the disease in which the treatment was begun, the better were the results obtained. The treatment was effective in both severe and mild cases. Fraenkel makes no mention of his death-rate; Rumpf lost two patients out of thirty—one by intestinal haemorrhage, the other by pneumonia.

The results reported for this treatment were so striking that the writer determined to test its therapeutic value. As the number of cases likely to come under observation in a few months would be small, it was decided to confine the study entirely to the typhoid cultures.

---

* Read before the Society of Alumni of Bellevue Hospital, December 5, 1894.
\(\dagger\) Deutsche med. Woch., No. 41, 1893.
\(\dagger\) Idem.
The thymus bouillon was prepared, as was Fraenkel’s, according to the method of Brieger, Kitasato, and Wassermann.* The thymus glands of calves were obtained as soon after death as possible, chopped very fine and mixed with distilled water, using for every gramme of the chopped glands two cubic centimetres of the water. This was allowed to stand in the ice box for sixteen to eighteen hours, then strained through cheese cloth and squeezed out as thoroughly as possible. This gave a cloudy mucilaginous fluid, which was alkalized with potassium hydroxide until not quite neutral to the phenolphthalein test, but distinctly alkaline to litmus. The fluid was then further diluted one third with water, and sterilized for half an hour in steam at 100° C. The fluid then became a grayish-brown color, and the coarse coagulated flocks were filtered off through absorbent cotton after the fluid cooled. The resulting fluid was of a milky, opalescent color, and, being put in small flasks, was sterilized in steam at 100° C. for two successive days. These flasks were inoculated from a broth-culture of a typhoid bacillus obtained fresh from a spleen of a patient dead from typhoid fever. These flasks were then put into the thermostat at 37° and allowed to grow for seventy-two hours; they were then sterilized by heating in a water bath at 62° to 63° C., for twenty to thirty minutes. They were then tested on agar plates, and, if sterile, were ready for use.

Twenty-eight cases were treated. Of these, I am indebted to Dr. Northrup for those treated in the Presbyterian Hospital; to Dr. Norrie for those at St. Luke’s; to Dr. Draper for those at Roosevelt; and to the courtesy of Dr. Dana and Dr. Wilcox, who allowed me to continue my treatment during their periods of service at Bellevue Hospital.

Of these twenty-eight cases, fifteen showed more or less improvement, which can, I think, be fairly attributed to the injection. Twelve did not improve under the injections, and one death occurred.

In the fifteen cases showing improvement the injections were begun usually about the tenth day, ranging from the sixth to the twentieth. At first in two cases it was tried as Fraenkel suggests, injecting half a cubic centimetre, and on the following day one cubic centimetre, and then, at the expiration of forty-eight hours, if the temperature did not show a decided fall, injecting two cubic centimetres; and then, if the temperature still remained high, repeating the injections at forty-eight-hour intervals, increasing the amount by one cubic centimetre at each injection. Under this plan the improvement was evident, but not marked. Therefore I changed the plan of treatment, varying it somewhat in certain cases, but, as a rule, injecting increasing amounts for four or five successive days, beginning with half or one cubic centimetre; then giving, at twenty-four-hour intervals, doses of two, three, or four, and then five cubic centimetres, as the case demanded; then waiting forty-eight hours, and, if the temperature rose again to 101° F., or over, repeating the five cubic centimetres, or even giving six or seven cubic centimetres. This gave much better results, both in regard to the temperature curve and in the general improvement of the patients.

In all cases the injections were made deep in the gluteal region, alternating on the right and left sides. In only one or two cases was there any local reaction, consisting of redness and tenderness, which subsided in one or two days.

The temperature curve follows the description given by Fraenkel. Sometimes there was, within thirty minutes to two hours after the injection, a rise of temperature with or without distinct chill, and at times this rise or this chill was followed by profuse sweating. In two cases the rise of temperature was accompanied with nausea and vomiting and headache. As a rule, after the third injection, the temperature curve showed a lower range, followed after the fifth injection by a decided fall of several degrees, even to normal, in the following twenty-four hours. The continuous type of fever curve often changed to the remittent type while falling. At times no abrupt fall occurred, but the fever ranged lower and gradually disappeared by a long lysis.

The pulse showed a decided improvement following the injections both in its frequency and in its force and tension. With the chill and rise of temperature after injections, as a rule, the pulse did not show a proportional increase in frequency.

The general condition of the patient showed the greatest improvement, the classical picture of the third week of typhoid being entirely absent. The mental condition improved; the patients lost their apathy and became bright, the sleep became more natural, the delirium ceased, and the diarrhoea stopped. When constipation was present instead of diarrhoea, the injections had no influence whatever upon it. Marked hunger appeared in several cases coincident with the fall of temperature. The tongue usually cleaned and became moist before the injections were completed. In one case, after the third injection, partial suppression occurred, the patient passing only six ounces of urine in twenty-four hours. This symptom disappeared in the following twenty-four hours, the patient showing no bad effects from it. Five cases of relapse occurred in the sixteen cases favorably affected by this treatment. These relapses were not treated in every case with further injections, but those so treated quickly subsided. The roseola, however, was not affected, and the spleen only slowly subsided.

In the twelve cases showing no benefit from the treatment, the injections were begun at a time varying from the ninth to the twenty-second day of the disease, averaging on the fifteenth day. This is five days later than in the group of improved cases, and bears out the statement of Rumpf that the earlier in the disease the injections are begun the more chance there is of a beneficial action. In three cases of this group where the injections were begun on the twentieth and twenty-second days of the disease the temperature fell rapidly after the injections, but it was so late in the disease that one can not be sure that convalescence would not have begun at that time had the injections been withheld. In the other eight cases there is no doubt that the injections did not result in any benefit to the patients.

* Zeitschrift für Hygiene and Infectiouskrankheiten, vol. xii, p. 147.
On the other hand, in no one of the twenty-eight cases was there any harmful effect observed due to the injections. The case that proved fatal was a very severe one, the patient being in an extremely poor general condition when the injections were begun. On the eighth day but three injections were given of one, two, and three cubic centimetres, respectively; tub baths were also given during and after the injections in this case, but the patient died from the severity of the disease three days after the last injection, and on the fifteenth day of the disease.

The cases here recorded were taken as they came to the hospitals, and were mild, moderately severe, and severe. The diagnosis was purely clinical.

During the past year three other authors have published small series of cases treated by this method. Von Jaksch,* in Prague, used the original thymus bouillon of Franckel and Rumpf, treating nine cases with the typhoid bouillon and eight with the pyocyaneus. In one severe case coming under his care in the second week, with a temperature of 104° to 105° F., after five injections with typhoid thymus bouillon the patient was apyretic and the temperature did not rise again. In the remaining eight cases so marked a result did not occur. It also was evident that with the pyocyaneus culture a continuous can be changed to a remittent fever, but in severe cases this result was not obtained. He did not obtain valuable results with the treatment, as he did not consider that he had so modified the typhoid that it proved of essential benefit to the patient, although he had shortened the duration of the disease. Moreover, the injections were unpleasant to the patients, as they often caused severe pain. In one severe case which came to autopsy, sterile pyocyaneus pus was found in the injection wound.

Kraus and Buswell,+ in Vienna, tried the pyocyaneus thymus bouillon in twelve cases. They injected into the thigh and had a limited lymphangitis follow and abscesses in two cases. Cases were severe and moderately severe, without complications, but with two deaths. The stage of the disease was the second or third week, so far as the history could prove this. Only three cases showed positive results on temperature. In four or five further cases such a supposition was fairly possible, in the rest it was quite out of the question. There was no influence on the curve as continuous or remittent. The pulse fell with the temperature; the diarrhoea did not improve, the roseola persisted, and the spleen continued large. Only one case showed marked general improvement, though this case showed no marked fall of temperature. In this case there was distinct increase of strength, and the stupor and nightly delirium disappeared.

These authors are not at all favorably impressed with the treatment.

In summing up the results in the cases recorded here, I certainly have not obtained the brilliant results alleged by Franckel and Rumpf. It seems, however, to have been of benefit in a little more than half the cases tried, and where it has benefited it certainly modified the severity, and in some cases shortened the duration of the disease. I wish to express my sincerest thanks to Dr. J. W. Brannan for his kindness in treating many of the cases and giving them to me to report, and to Dr. T. M. Prudden for his many valuable suggestions to me.

**ABSCESS OF THE BRAIN.**

*By N. B. Carson, M.D., St. Louis.*

An eminent surgeon of London, ten years ago, is said by McEwan to have asserted that to see an abscess of the brain, even post mortem, was an event of a lifetime. This seems strange, as I am quite sure there is not a surgeon in this city of twenty years' experience who has not seen more than one case of abscess of the brain during the first ten years of his practice, and the opportunities afforded here are by no means to be compared with those of the great city of London. During twenty odd years of practice I have seen quite a number of abscesses in this region, arising, some of them from injury, some of them (by far the greatest number) from ear disease, one from nasal trouble, and one, a recent case, from a most unique cause—a bite of a wood tick upon the scalp.

The first case of the kind that I now call to mind was under my care in the St. Louis Mulrany Hospital in the year 1872, during the absence of Dr. Gregory, whose case it was:

The patient, a boy about seven years of age, had fallen some months before from the third story window to the pavement below, striking upon the top and side of the head over the parietal region. The skull was very badly mashed, and at the time of the injury and subsequently a number of fragments of the cranium were taken away. When he was brought to the hospital there was a large suppurating wound through which the brain substance protruded (hernia cerebri). I, at various times, removed pieces of dead bone and sliced off portions of the protruding brain substance. At one point (I think it was behind the Iolandi fissure), after some days, I noticed a soft fluctuating spot, which I accidentally opened while examining. As a result a considerable quantity of pus was discharged. I did not attempt to wash or drain the cavity; I did not even introduce a probe; I thought I had already done enough. Suffice it to say that after many weeks in the hospital the child made a good recovery and left with the wound almost closed.

Another case occurred at the same time that the one described above was under my observation.

The patient, a young man about twenty-two or twenty-three years of age, a waiter by occupation, had, in a quarrel, been struck with a fork, the prongs of which were broken off, one in the soft tissues, where it had formed an abscess, and two had been driven through the bone into the brain substance. The region of the injury was the left temple. I saw the case three weeks after the stabbing. The prong buried in the soft tissue had been removed by the physician first in attendance. The second prong I removed after I was called. This one went through the bone into the brain at least an inch. The third

* * *
was removed post mortem, and, like the one I had removed, extended through the bone about an inch into a large abscess in the bone substance. There were absolutely no symptoms of cerebral disturbance until within three or four days of the patient's death, when he commenced complaining of severe headache, and it was noticed that he was more or less drowsy and indifferent to his surroundings. This condition gradually increased until he became profoundly comatose. The diagnosis of brain abscess was made by Dr. Hodgen, who saw the case with me in consultation a short time before the patient's death. Upon removing the scalp, after death, the third prong of the fork was found where it had been broken off almost even with the surface of the bone. Upon removing the calvarium an abscess was found involving the frontal lobes.

Still another case is worth mentioning, that of a child of four years of age, who suffered from nasal catarrh, the result of an injury. The infection extended through the cribiform plate of the ethmoid to the brain and formed an abscess which resulted in death.

Besides these cases, which I saw in ante-localizing days, I have seen a number of abscesses of the brain the result of disease of the middle ear, and the majority of them have been in adults. Within a period extending a little over three years I have seen nine cases of abscess of the brain, and of this number eight have resulted from disease of the middle ear. Of all these cases, two are of particular interest. I deem them worthy of a detailed description:

Last January I was called upon to open the mastoid antrum on account of a suppurating inflammation of the middle ear in a lad of fifteen years. I had not seen the case until I went to the house to operate, when I learned that the patient had had for several years, off and on, a discharge from the ear. Two weeks or thereabouts before I saw him he had had an attack of the old trouble, and Dr. Lemoine, the family physician, sent for Dr. Jones, who treated him for some days until the ear symptoms were much improved. Again the pain in the ear became intense and Dr. Jones was called and decided that the antrum should be opened. I was then sent for and found the ear discharging freely; while pressure over the mastoid caused pain, there was no perceptible swelling. The pulse was 100; the temperature before my arrival was over 102°. The operation was done at once, the antrum and middle ear exposed. That evening the temperature was normal and the pulse 80. The night after the operation was passed well; once during the night he vomited, but this was attributed to the cedema form. During the next day he was bright and seemed much better, except that he complained of pain in the back of the head. The pulse was slow, only 68, but otherwise good. The temperature during the day was a little over 99°; there was also more or less vomiting. I now began to fear abscess of the brain. The second night was not as good as the first, although he rested fairly well. The next morning he was obverse, and it was some time before I could get him to notice me, but this I attributed to the fact that I was about to draw the wound and he had no kindly feelings toward me, as after I had finished he was bright and talkative, asking me a number of questions. I forgot to mention that I dressed the wound daily and that the washing out of the ear always caused severe pain in the head, which subsided immediately.

At my evening visit the nurse told me that he had had a good day, seeming more like himself than he had for some time. The vomiting, however, had increased and the temperature fell below normal; the vomiting was always preceded by nausea and generally followed the introduction of food into the stomo, of which during the day he had taken a fair amount. He still complained of pain in the back of the neck. The third night he was very restless. I now made up my mind that we had an abscess of the brain to deal with. The next morning he was wild and very profane and vulgar in his language. The temperature was now most of the time subnormal, while the pulse varied from 68 to 78 and was small and compressible. The tendon reflexes were exaggerated and vomiting continued, and he would frequently cry out on account of the pain in the head. Emaciation was marked.

That evening, the third day after the operation, I met Dr. Bremer, Dr. Lemoine, and Dr. Jones in consultation, and they agreed with me as to the presence of an abscess in the brain, but it was decided that the patient was too weak for any operative interference at that time. Heart tones, nutrient enemata, etc., were ordered in hopes of improving the patient's condition. The next day the patient seemed somewhat better, while the cerebral symptoms remained unchanged. The two days following showed little or no change.

After another consultation with the same gentlemen it was decided to operate as a forlorn hope. Everything was explained to the parents and their consent obtained. One week from the time of the first operation, an opening was made through the cranium an inch and a quarter behind the middle of the external meatus and three fourths of an inch above Reed's base line. Into this opening the brain protruded and was entirely free from pulsation. The temporal lobes were first explored with negative results. The opening was then enlarged downward with the rongeur forceps and the cerebellum explored, when there was a gush of pus. With a forceps following the director this opening in the brain was enlarged, and the abscess cavity emptied. The abscess must have involved almost the entire cerebellar hemisphere, judging from the quantity of pus poured out. The patient was returned to bed in a very bad condition, and survived the operation only an hour and a half.

This case was remarkable only in the fact that an abscess of that size could exist and at the same time manifest comparatively few symptoms. I was assured by the different members of the family that they had at no time noticed any change in his disposition. Another remarkable feature about the case is, that he was able to go through, without fault, diluent gymnastic exercises, dance, play baseball, football, etc.

The following very unique case came under my care at the St. Louis Manhattan Hospital in the latter part of June last:

The patient, a well-developed boy of eight years of age, was a resident of the southern portion of this State. From his history it was learned that about the 11th day of last May he had been bitten on the right side of the head by an ordinary wood tick, common to this region. About a week later it was noticed that the part was inflamed and that the patient had fever. This condition lasted for three weeks, when an abscess formed under the scalp limited by the eyebrows in front and extending almost to the parietal eminence behind, the median line above, and the zygomatic arch below. The abscess was opened by the attending physician, and healed rapidly after it had been emptied. On the 8th of June he was seized with a spasm which involved, first the muscles about the outer angle of the left eye, then the angle of the mouth, then the arm, and finally the leg of the same side. This condition is said to have lasted five hours, during which time the patient was speechless, and, part of the time at least, unconscious. This left the entire left side more or less paretic, but especially about the angle of the mouth.
On the 22d of June he had another spasm, not so severe as the preceding one. This lasted three hours, during all of which time the patient retained consciousness and the power of speech, but when it passed off, the paresis of the face was almost complete, while that of the body was decidedly increased. This spasm began with twitching of the angle of the mouth; from there it went to the eye, then to the shoulder, arm, and leg. About this time an abscess in the apex of the left lung was discovered which opened into a bronchial tube and discharged. I saw him first on the 29th of June. At that time he was much wasted. Upon physical examination, found the skin pale, the muscles soft and flabby. On the right side of the head was a soft, fluctuating tumor, an abscess of about the size of a large hickory nut. The face and right side of the body were almost completely paralyzed. The family history was good, and up to a short time before he was bitten he had been healthy and strong. The mother stated that she had noticed some time before this that he was languid and not in his usual good health, and complained of feeling tired, etc. The heart was healthy. The pupils were found to respond normally. The tendon reflexes increased, more marked on the left side; ankle and knee clonus marked on the left side, slight on right; the senses of touch and sensation were unimpaired. The pulse was 81, irregular, intermitting, a beat now and then, becoming alternatingly fast and then very slow. He was also very impatient, not brooking delay, and complained of hunger continually, the appetite never seeming to be gratified. The mother stated that he had always been of a good disposition, and while he possessed a good appetite, it was inordinate.

On the 4th of July the abscess on the scalp was opened by one of my assistants and washed. An examination of the urine showed hylane casts with adherent crystals of the phosphates; no albumin, crystals of the urates, phosphates, and indican. Dr. Le Beau and Dr. Wolfner, who kindly examined the eyes, reported July 6th, that when at rest the eyes were turned upward and to the left; the pupils were slightly dilated and responded promptly to light; the fundus was normal, except the disc, which had a watery, suffused look suggesting edema, but there was absolutely no swelling. The veins were somewhat enlarged, while the arteries were normal.

On the 9th of July I operated and, upon removing the scalp, found that the bone at the site of the abscess, above referred to, had been entirely destroyed so as to expose the dura; the opening was enlarged downward and forward. The dura upon its outer surface was covered with a dirty grayish exudation; when incised it was found to be much thickened, while its under surface was perfectly healthy, as were also the underlying membranes and brain surface. When the dura was incised, the brain substance protruded to such an extent that I feared it might rupture. There was an entire absence of pulsation. Upon introducing a small grooved director downward and forward there was a discharge of yellow, healthy-looking pus (about two ounces). The opening was enlarged by carrying forceps along the director; the pus was freely discharged, the cavity washed, and a drain introduced. The patient made a good but slow recovery, and when he left the hospital on August 9th he was able to walk with little assistance. The wound had entirely healed except at one point, from which came a slight discharge due to a small necrosis of the cranium.

November 23d.—The patient visited me to-day entirely recovered in general health, all signs of sickness having disappeared, except that he is totally blind, a condition which has come on gradually since his return home. Dr. Le Beau and Dr. Wolfner again examined the eyes and report that they found the pupils widely dilated without any perception of light; the fundus mottled with atrophic choroiditis spots, the disc atrophic.

Dr. Ravold, who took the pus discharged from the abscess at the time of the operation, reports that he got a pure culture of Staphylococcus pyogenes aureus, thus confirming the diagnosis of infective abscess of the brain and lung.

Now the question presents itself as to how this infection reached the brain, as we have seen that the under surface of the dura was perfectly healthy, as was also the underlying membrane as well as the brain surface. Was its position a coincidence, or was it a direct infection from the abscess under the scalp? I think it was direct, and occurred through the communicating veins which, in facial life, extend through the dura into the brain. Some of these veins, like similar vessels in other parts of the body, may have remained patent and conveyed the micro-organism from the surface to the interior of the brain.

In this case we also have a confirmation of the theory as to the location of motion and the senses of touch and sensation; the area in front of the Rolandic fissure being purely motor, while the tactile senses and sensation are said to be confined to the posterior regions. Here the abscess was, so far as it was possible to determine, limited to the two lower frontal convolutions, and precentral, and as a result the motor functions were markedly involved, while sensation and the tactile senses remained perfect, a most careful examination having been made to determine this point.

How is the resulting blindness to be explained? There was evidently a certain amount of encephalitis, involving, in all probability, a great portion of the anterior part of the respective hemisphere, together with the optic commissure, and the blindness was possibly a result of the inflammatory changes in the commissure and optic nerves.

A similar case is described by Williamson in the British Medical Journal for February 1, 1891.

I forgot to mention that when the patient left the hospital there was a large cerebral hernia. This hernia was still present when I saw him in November, but had decidedly diminished. Some time after his return home a small piece of dead bone was removed from the sinus, existing when he was discharged from the hospital, after which it rapidly healed.

---

REPORT OF A CASE OF VERRUCAE ACUMINATE OF THE PENIS, CAUSING, THROUGH THE ABSORPTION OF THEIR SEPTIC EXUDATION, PHIMOSIS AND LYMPHANGITIS, FOLLOWED BY A DORSAL SLOUGH.*

BY RAMON GUITÉRAS, M.D.,
PROFESSOR OF ANATOMY AND OPERATIVE SURGERY
AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL;
CONSULTING SURGEON TO THE FRENCH HOSPITAL;
VISITING SURGEON TO THE COLUMBUS AND CITY HOSPITALS.

The patient, C. L., aged eighteen years, French, an omnibus in an uptown restaurant, presented himself at the French Hospital of this city, in February last, for treatment.

History.—The patient stated that he had never had any venereal disease; that six months ago, two weeks after connec-

* Presented before the Society of Dermatology and Genito-urinary Surgery, April 15, 1894.
tion, he noticed a growth under the prepuce near the frenum, which caused him no pain and very little inconvenience. This continued to increase slowly in size until a condition of partial phimosis existed. About a month ago, or one week before entering the hospital, the dorsum of his penis became red, inflamed, swollen, and painful. This inflammatory condition increased, and rapidly involved the entire prepuce and extended well up on the organ. It was very painful and tender.

Examination on entering the Hospital.—The patient was a pale, lymphatic-looking boy. Locally he revealed an organ very much enlarged and having an inflamed, angry look. The circumference, measured over the site of the corona, was eight inches and a half. The prepuce was very edematous, especially on its outer surface, where it measured an inch and a quarter in thickness. The tissues of the preputial margin were bluish in color and very tense. Upon the dorsum, following the course of the dorsal lymphatics, was a red and angrily looking area of inflammation, evidently a lymphangitis, extending to within an inch of the pubes and nearly encircling the organ. On retracting the prepuce as much as possible, cauliflower excrescences were disclosed growing from the glans and balano-preputial membrane, extending backward from the everted lips of the meatus urinarius and the margin of the prepuce in such masses that the glans was almost hidden from view. From this inflamed subpreputial area a foul, fetid, purulent discharge oozed. The inguinal glands were not enlarged. This condition was evidently due to an absorption of the septic matter discharged from the verruca.

Treatment.—Subpreputial irrigations of one in fifteen thousand bichloride solution every three hours, and a dressing of lead and opium wash externally.

The condition rapidly grew worse; a dorsal abscess developed and burst subpreputially, thus increasing the foul discharge already existing. Two days later a slough of that portion of the dorsal tissue over the course of the dorsal chain of lymphatics and just behind the corona occurred, leaving a gangrenous communication between the outer and inner preputial surfaces about half an inch in diameter. The margins of this opening were covered by a nasty slough, and gave rise to an exceedingly fetid and necrotic odor. A dorsal incision was then made from the margin of the prepuce into the area of slough. The edges of the wound were touched with a saturated solution of nitrate of silver. The balano-preputial mucous membrane, the inflamed verrucce, and the sloughing and gangrenous tissue into which the dorsal incision opened were then washed thoroughly with peroxide of hydrogen and dressed with a powder of charcoal and iodoform, equal parts, and cotton pledges. For two or three days after this the organ was irrigated twice a day with a solution of permanganate of potassium and dressed with charcoal and iodoform. When the fistula had disappeared the charcoal and iodoform dressing was changed for one of equal parts of boric acid, bismuth, and calomel.

Two weeks ago, or a week after the dorsal incision, the patient was etherized and the verrucae were removed from the glans and balano-preputial membrane by a sharp curette. As considerable hemorrhage occurred during the curettage, a ligature was put about the penis until the operation was finished, when the organ was irrigated with a hot bichloride solution, strength 1 to 2,000, and dressed with pledges soaked in the same solution. A bandage of bichloride gauze was then wound around the organ, thus making pressure on the glans and balano-preputial membrane both internally and externally. After this the patient was irrigated twice a day with a 1-to-2,000 bichloride solution, and dressed with a powder of equal parts of boric acid, bismuth, and calomel, with cotton pledges. One week ago, the curedt surface having healed, circumcision was performed. The parts were afterward dressed with iodoform and iodoform gauze.

I now present him to you, gentlemen, for examination, perfectly cured. The healing after the circumcision was by first intention, notwithstanding the septic condition in which the organ had previously been. There is now no evidence of any verruca, and with the exception of a slight thickened condition on the lower surface there is nothing to show the trouble that he has so recently gone through with.

THE DIPHTHERIA BACILLUS IN A PNEUMONIC LUNG.

INTRODUCTORY COMMUNICATION.

By A. P. OHLMACHER, M.D., PATHOLOGIST TO THE CITY HOSPITAL, CLEVELAND, OHIO.

The novel feature of this case lies in the discovery of the diphtheria bacillus in the substance of the affected lung in a case of primary, right-sided, lobar pneumonia, complicated with an acute purulent meningitis.

In brief, the history of the case* is as follows:

Clinical Abstract.—H. S., forty-six years of age, was transferred from the male insane department of the infirmary to the wards of the City Hospital, and assigned to the service of Dr. A. F. Spurney, January 30, 1895. On account of the violent type of his insanity very little could be learned from the patient concerning the present illness, which was noted at least two days before he was removed to the hospital. On admission, the pulse was 110, temperature 102-4° F., respiration quickened and superficial, and a marked dullness was discovered over the lower lobe of the right lung. The area of dullness gradually extended until the whole right lung became involved, and all the physical signs of pulmonary solidification were pronounced; the temperature curve was irregular, with morning remissions; the patient became unusually delirious the last two days of his illness, and he died on February 11th. Nothing in the patient's symptoms directed attention to his throat, and no history of a previous throat trouble could be obtained. No false membrane was noted in the mouth or on the gums.

Autopsy Abstract.—The post-mortem examination was made twelve hours after death, with all the thoroughness possible with the inadequate facilities afforded by this hospital. Omitting all details, it may be said that the prominent gross pathological lesions were a complete gray hepatization of the right lung, which was fixed in its pleural cavity by extensive recent fibrinous adhesions, and an exquisitely marked, acute, purulent meningitis. No examination of the mouth or throat was made.

During the progress of the autopsy several tubes of Loeffler's blood-serum culture medium were inoculated from the substance of the affected lung and from the meningeal pus, with the observance of rigid bacteriological precautions. Cover-glass smears were made from the pus under the pia mater and from the tissue of the diseased lung. Pieces of the various tissues were fixed in corrosive-sublimae solution and preserved for microscopic study.

Bacteriological Abstract.—The smear preparations made

* I am indebted to Dr. Frost, resident physician at the Cleveland City Hospital, for the clinical data, of which the merest outline is here given.
TRACHEOTOMY IN EMERGENCIES.

By HUGH H. YOUNG, A. M., M. D.,
ASSISTANT IN SURGERY, JOHNS HOPKINS HOSPITAL Dispensary, BALTIMORE.

The ordinary operation of tracheotomy is quite simple, with a full set of appropriate instruments at hand, but often the necessity for the operation arises suddenly and when we are not prepared for it, and undoubtedly many a child with laryngeal diphtheria has gone to its grave because the physician feared to do the operation without the customary instruments and tubes.

In a recent case I was placed in such a position, with asphyxia approaching and no instruments at my command. I therefore offer the means I adopted, with the hope that it may assist some fellow-practitioner in a similar strait:

A child two years and a half old came into my hands with diphtheria of three days' standing. The membrane could be seen across the lower half of the pharynx, and the larynx was so badly involved that the child could not speak, and the respiration was rapid and wheezing in character. With the assistance of Dr. P. J. F. Martenet, I injected a bottle of No. 1 Behring's antitoxine. On the next morning the child was much improved, and the voice and breathing better. We injected another dose of antitoxine, and left, considering the child almost out of danger. When I returned at 9 p.m., however, the condition was much worse, the respiration gasping, and the child's face becoming cyanotic, showing gradually increasing occlusion of the trachea or larynx.

Not being prepared for intubation or tracheotomy, and being in the country five miles from any instrument house, we had given up all hopes of the child's recovery, when, finding a small glass tube, the thought struck me that we might utilize it for a tube.

This tube was of about the size of a small lead pencil. Removing the chimney from a lamp and twirling the tube rapidly in the flame, I was soon able to bend it into the proper curve for a tracheotomy tube. It was then cut off by making a nick in it with a file or dull knife and breaking over the ends of the thumbs. The rough ends were rounded by holding in the flame.

After injecting cocaine subcutaneously in the median line of the neck, I made an incision down to the trachea with a pocket scalpel which I happened to have.

I may say that as I desired to avoid the isthmus of the thyroid and go below it, the incision was made from the second tracheal ring downward for an inch and a half.

All hemorrhage having been stopped by hot compresses, a longitudinal incision three quarters of an inch long was then made into the trachea, and the child turned on its belly so that no blood would flow into the trachea.

Hemorrhage having ceased, the child was turned on its back and the bent glass tube inserted, and in a few minutes the breathing became more regular, the cyanosis disappeared, and the child went to sleep.

As it now was, the tube had to be held in place, so I determined to improvise another which could be fastened around the neck with tapes.

So, bending another tube as before, I wrapped it with thread to prevent breaking. A cross piece was then made of wood half an inch wide and an inch long, a hole being cut in the middle to receive the glass tube. Holes were also cut in each end to receive the tapes. Having fastened the cross piece to the tube by wrapping it with thread, this improvised tracheotomy tube was inserted into the trachea and secured in position by the tapes around the neck.

The child slept well all night, and by the next evening the antitoxine had got in its work, and the larynx was so cleared of membrane that the tube was removed entirely. In a few days recovery was complete.

As tracheotomy wounds are always infected, it is the custom to allow them to heal by granulation and not to bring the edges together by sutures.

In this case, having been able to stop the suppuration by vigorous antiseptic treatment, I decided to risk it, and drew the edges of the broad, gaping wound together with sutures. The result was very satisfactory; no stitch-abscess or any suppuration followed, and in place of a broad, ugly scar a small linear one resulted.

It would seem that many unsightly scars from infected wounds about the face and neck could be avoided by suturing as soon as suppuration had been cured. In this case the edges were well cyanized by nitrate of silver before being drawn together.
THE NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, APRIL 27, 1895.

THE AMERICAN MEDICAL ASSOCIATION.

Early in May, before another issue of the Journal will have had time to reach the more distant of our readers, the great national organization will be in session in Baltimore. Many indications point to a meeting more than ordinarily noteworthy. In the first place, the attendance is likely, we think, to be unusually large. Baltimore is an exceptionally attractive town, and the hospitality and geniality of its people are proverbial. A sojourn in Baltimore for almost any purpose is a pleasure in itself. Add to this the reflection that the members of a profession are to meet each other, many of them for the first time, and the thought is at once raised that the attractions of the occasion will prove more potent than those that are wont to attend great gatherings. Great as are Baltimore’s own beauties, it is not they alone that make it a peculiarly winsome place for a meeting that is to last for several days, but its fertility in opportunities for short excursions to localities that every American longs to see once in his lifetime comes into play also. The national capital, the home of the incomparable Washington, and the Naval Academy are all within easy reach. It is, indeed, difficult to think of another city in the country that could serve as the starting-point of so many short jaunts to places of such surpassing interest.

But, quite apart from the matter of the place of meeting, there seems to be a feeling pervading the profession that this year’s sessions of the American Medical Association are to be pleasanter, more profitable, and perhaps more important than they commonly are. Men appear to regard it as more than ever their duty to be present at the meeting. Precisely why this is the case it would not be easy to say; perhaps it would be profitless to inquire. Whatever may be the reason of it, the very existence of the feeling—and we are sure it does exist—is a cause of real gratification. We expect to record the fact that the Baltimore meeting has given unusual satisfaction to the profession. We look to see its proceedings characterized by dignity and harmony; to see the association strengthen its hold, already firm, on the hearts of the individual medical men of the United States; to see its resources notably augmented, so as to enable its journal to keep on in the path of improvement that has of late been very plainly discernible in its appearance; in short, to see the representative organization of the American medical profession make a stride on a course that has always had a high goal as its object.

MINOR PARAGRAPHS.

THE LICENSE TO PRACTICE IN ILLINOIS.

In another column we print some resolutions recently passed by the faculty of the Northwestern University Woman’s Medical School reflecting upon the Illinois State Board of Health for having, as is alleged, granted licenses to candidates who had been unable to pass the examination for the degree of doctor of medicine in that or some other medical school. We can not suppose that such a public criticism of the board would be made by a college faculty unless there were facts to warrant it, but it is to be hoped that the board will speedily do away with all ground for complaint in the matter, particularly when we call to mind its past reputation as a supporter of high standards.

A PHYSICIAN ON ORIENTAL MATTERS.

We always feel gratified when a member of the medical profession goes beyond the limits of his calling to undertake any honorable and beneficent work for the community, whether in literature, in public speaking, or in politics. We are therefore pleased to learn that this (Saturday) evening Dr. William II. Thomson is to entertain his fellow-members of the Century Club with a paper entitled Arabia, Islam, and the Eastern Question.

A NEW MONTHLY JOURNAL.

A new journal of general medicine and surgery, entitled Medicine, has made its appearance in Detroit. The first number is dated April, 1895. It contains sixty-four pages of reading matter, including original articles by Dr. W. L. Baun, Dr. D. A. K. Steele, Dr. H. A. Hare, Dr. G. F. Lydstor, Dr. W. S. Christopher, and Dr. S. S. Bishop, also book notices and abstracts. It is edited by Dr. Harold N. Moyer, of Chicago.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending April 23, 1895:

The Medical Association of Georgia.—At the recent annual meeting a section in ophthalmology was organized. The chairman of the section is Dr. J. Lawton Hiers, of Savannah.

The New York Lying-in Asylum.—Dr. Samuel Marx and Dr. J. Clifton Edgar have been appointed visiting obstetricians to the asylum.

The Association of Acting Assistant Surgeons of the United States Army will hold a special meeting in Baltimore on the 8th of May.

The College of Physicians and Surgeons of Chicago.—We learn that Dr. Bayard Holmes has again undertaken the office of dean of the faculty.
The National Academy of Sciences.—It is announced that
Dr. William H. Welch, of Baltimore, has been elected a member of the academy.

Change of Address.—Dr. Edmund C. Wendt, to No. 118
West Seventy-ninth Street, New York.

Army Intelligence.—Official List of Changes in the Sta-
tions and Duties of Officers serving in the Medical Department,
United States Army, from April 14 to April 29, 1895:

Eber, Rudolph G., Captain and Assistant Surgeon, is granted
leave of absence for two months, to take effect on being re-
lieved from duty at Fort Huachuca, Arizona.

Kendall, William P., Captain and Assistant Surgeon, is granted
leave of absence for six months, with permission to go be-
yond sea, to take effect upon his relief; from duty at Fort
Columbus, New York Harbor.

Smith, Joseph R., Colonel and Assistant Surgeon General. By
direction of the President the retirement from active service,
April 18, 1895, is announced.

Naval Intelligence.—Official List of Changes in the Medi-
cal Corps of the United States Navy for the week ending April
20, 1895:

De Valin, C. M., Assistant Surgeon. Detached from the U. S.
Steamer Vesuvius and ordered to the U. S. Revenue
Steamer Vermont.

Lowndes, C. H. T., Passed Assistant Surgeon. Detached from
the Coast Survey Steamer Hassler and ordered to the Mare
Island Hospital.

Pickrell, G. M., Passed Assistant Surgeon. Detached from
the U. S. Steamer Newark, ordered home, and granted two
months' leave of absence.

Smith, Howard, Surgeon, retired. His leave of absence is ex-
tended six months, with permission to remain out of the
United States.

Stone, L. H., Assistant Surgeon. Ordered to the U. S. Steamer
Newark.

Marine-Hospital Service.—Official List of the Changes of
Stations and Duties of Medical Officers of the United States
Marine-Hospital Service for the Fifteen Days ending April
15, 1895:

Purvisance, George, Surgeon. Detailed as chairman of retire-
ning board for physical examination of officers of Revenue
Cutter Service. April 8, 1895.

Austin, W. W., Surgeon. Detailed as member of retiring board
for physical examination of officers of Revenue Cutter Serv-
vice. April 8, 1895.

Carter, H. R. Detailed as recorder of retiring board for physi-
cal examination of officers of Revenue Cutter Service.
April 8, 1895.

Glennan, A. H., Passed Assistant Surgeon. Granted leave of
absence for three days. April 9, 1895.

Stoner, J. B., Passed Assistant Surgeon. When relieved, to
proceed to Philadelphia, Pa., for duty. April 5, 1895.

Guteras, G. M., Passed Assistant Surgeon. Granted leave of
absence for six days. April 5 and 8, 1895.

Perry, J. C., Passed Assistant Surgeon. To proceed to Port-
land, Ore., and assume command of service. April 5, 1895.

Eager, J. M., Passed Assistant Surgeon. To proceed to Gulf
Quarantine Station for temporary duty. April 5, 1895.

Stewart, W. J. S., Assistant Surgeon. To proceed to Phila-
delphia, Pa., for temporary duty. April 9, 1895.

Norman, Seaton, Assistant Surgeon. To proceed to Norfolk,
Va., for temporary duty. April 9, 1895.

Cumming, H. S., Assistant Surgeon. To proceed to Boston,
Mass., for temporary duty. April 9, 1895.

Society Meetings for the Coming Week:

**Wednesday, May 1st:**
- State Medical Society of Arkansas (first day—Little Rock);
- Connecticut Medical Society (first day—New Haven);
- New York Academy of Medicine (Section in Public Health);
- Society of Alumni of Bellevue Hospital;
- Harlem Medical Association of the City of New York;
- Medical Microscopical Society of Brooklyn; Essex, North
annual—Haverhill, and Plymouth (annual), Mass., District
Medical Societies; Penobscot, Me., County Medical Society
(Bangor); Bridgeport, Conn., Medical Association.

**Thursday, May 2d:**
- State Medical Society of Arkansas (second day);
- Connecticut Medical Society (second day);
- New York Academy of Medicine;
- Brooklyn Surgical Society;
- Society of Physicians of the Village of Canandaigua, N. Y.;
- Boston Medico-psychological Association;
- Medical Society of the County of Orleans (semi-annual—Albion, N. Y.;
Ocean, N. J., County Medical Society (Tom's River);
Cuyahoga, O., County Medical Society;
- Obstetrical Society of Philadelphia;
- United States Naval Medical Society (Washington).

**Friday, May 3d:**
- State Medical Society of Arkansas (third day);
- Connecticut Medical Society (third day);
- Practitioners Society of New York (private);
- Baltimore Clinical Society.

**Saturday, May 4th:**
- Clinical Society of the New York Postgraduate Medical School and Hospital;
- Manhattan Medical and Surgical Society, New York (private);
- Miller's River, Mass., Medical Society.

Births, Marriages, and Deaths.

**Married.**

**Baldwin—Field.**—In New York, on Wednesday, April
24th, Dr. Frederick A. Baldwin and Miss Mary E. Field.

**Lambert—Cheney.**—In South Manchester, Conn., on Tues-
day, April 23d, Dr. Alexander Lambert, of New York, and
Miss Ellen W. Cheney.

**McCoy—Sessums.**—In Columbus, Miss., on Wednesday,
April 17th, Dr. Ambrose McCoy, of Jackson, Tenn., and
Miss Mamie Sessums, of Columbus.

**Died.**

**Dickson.**—In Pittsburgh, on Saturday, April 20th, Dr.
Joseph N. Dickson.

**Lawton.**—In Rome, N. Y., on Thursday, April 18th, Dr.
Elon J. Lawton, in his sixtieth year.

**Madden.**—In Woonsocket, R. I., on Sunday, April 21st,
Dr. P. H. Madden, in his sixty-seventh year.

**Wade.**—In Irvington, N. J., on Saturday, April 20th, Dr.
Joseph L. Wade, aged sixty-six years.

Letters to the Editor.

**The Effect of Serum Injections on the Blood.**

New York, April 15, 1895.

To the Editor of the New York Medical Journal:

Sir: In the last issue of the Journal I find among the ob-
jections to the injection of antitoxine serum the possibility of
its globulicald action. Dr. Winters exclaimed: "Horse serum dissolved human blood corporcles," and Dr. Armstrong states in his letter that those who heard Dr. Winter's criticism "can not but feel that an important factor has been overlooked in the consideration of the treatment of diphtheria with this substance (antitoxine serum), and that factor is the globulicald power of alien serum on the blood of an animal into which it is injected." I am quite sure that the gentleman erred on this point. Here are my reasons:

1. All statements on the detrimental effect of heterogeneous blood have reference only to the intravenous transfusion with the blood of another species; as yet no one has ever raised the contention that the subcutaneous injection of foreign blood showed globulicald effects. Even for the peritoneal cavity, from which absorption certainly occurs far more rapidly than from the subcutaneous tissue, Hayens, the authority cited by Dr. Armstrong, says that the infusion of alien blood into it is of no detriment to the blood of the recipient (Compt. rend., t. xvii, No. 12). As Dr. Armstrong's quotations deal only with transfusion (or direct contact of the heterogeneous blood), he is apparently not conscious of the fact that he is confounding intravenous with hypodermic injections.

2. Even in intravenous transfusion the fatal effect depends largely upon the quantity of the injected heterogeneous blood. According to Ponfick (Virchow's Archiv, vol. lixi, p. 303), dogs died from transfusion of sheep's blood after two hours, if the proportion was 32 grammes of the transfused blood to 1,000 grammes of the weight of the receiving animal; after nine hours the proportion was 20 to 1,000; after fifteen hours, 14 to 1,000; if 10 to 1,000 was taken, no dog died from the effects of transfusion. Now let us assume that the weight of the seventeen-year-old Miss Valentine, of Brooklyn, was about 100 pounds = 50,000 grammes. Ten grammes of the injected anti-toxine serum makes only 1/1000! Is there in the entire literature on this subject (by the way not since Landois, 1875, but since Dumas and Prevost, Annales de chimie, 1821) a report of a death of an animal or a human being occurring after transfusion of such a minimal quantity of foreign blood, and occurring a few minutes after the injection?

3. Since the introduction of the experimental study and the practical preparation and application of the diphtheria anti-toxine, the horse serum has been injected subcutaneously into rabbits and guinea-pigs many thousand times, certainly more often than in all the experiments upon transfusion taken together. As is well known, the rabbit is the most sensitive of all animals to foreign blood; nevertheless, not even once was bloody urine observed after the injection. Is not that proof enough that the globulicald powers of the horse serum do not come at all into consideration in the subcutaneous injection of the diphtheria anti-toxine? The harmlessness of the subcutaneous injections of heterogeneous blood serum is probably due partly to the slow absorption from the subcutaneous tissue, and partly to the fact that the foreign blood, while passing the lymphatics, takes or gives up a quantity of certain salts which, according to H. Buchner (Centrallbl. f. Physiologie, 1893, No. 7), are essential for the globulicald power of the alinecs.

And now one question. The facts concerning the globulicald character of the heterogeneous blood serum are stated in many text-books of physiology, and it is expected of every student of medicine to know something about them. Now, is it justifiable to assume, as Dr. Winters and Dr. Armstrong do, that the men who for years made a special study of the blood as a carrier of germicidal properties and acquired immunity will overlook such a factor of elementary knowledge, a knowledge which could be acquired in a few minutes from any textbook? One of the men is P. Ehrlich, a world-wide acknowledged authority on the blood. And it so happens that the first publication of Ehrlich, in 1875, was a study of the effects of the subcutaneous injection of blood! S. J. Meltzer, M. D.

THE ANTITOXINE TREATMENT OF DIPHTHERIA.

OWATONNA, MINN., April 15, 1895.

To the Editor of the New York Medical Journal:

Sir: I have just been reading, in the Journal of April 13th, Dr. Winter's criticism of the value of antitoxine serum in diphtheria, and comparing it with a paper read before the Pediatric Section of the New York Academy of Medicine, November 7, 1894, by A. Campbell White, M. D. Dr. Winters bases his opinion, as given, upon "three months of daily observation in the Willard Parker Hospital." Dr. White also gives an opinion "based upon a series of cases treated at Willard Parker Hospital with antitoxine Schering."

I will only quote slightly from each:

Dr. Winters says: "In fact, a careful study of the individual cases of diphtheria treated with the antitoxine in the Willard Parker Hospital would show that there had been no relation between the antitoxine treatment and the recovery."

Dr. White says: "The first question—Does antitoxine accomplish any appreciable good results in diphtheria?—judging from our own twenty cases alone, can be answered decidedly in the affirmative."

Any interested person can read the two reports and put in a valuable half-hour wondering how two able observers, working in the same hospital, arrived at such conflicting conclusions.

A. B. Stewart, M. D.

THE EFFECT OF FREEZING ON DIPHTHERIA ANTITOXINE

New York, April 8, 1895.

To the Editor of the New York Medical Journal:

Sir: In the New York Medical Journal of April 6th Dr. James J. Mapes, of the Nursery and Child's Hospital, this city, in a letter to the editor warns against the cloudy serum of Behring at present in the market of New York. As some mention is made therein that freezing may have been the cause, we would not fail to acquaint you with the experiments which Dr. Aronson made in the Schering laboratories with his serum. He exposed diphtheria antitoxine (Schering's) to the low temperature of —25° to —35° Celsius (—13° to —22° F.), and found that when the solution became liquid again its efficacy was not in the slightest affected. The liquid became only more opalescent, but no insoluble substances separated and it showed absolutely no sediment after two days' standing. These experiments were made last February, as you will see from the inclosed copy of a German letter of Dr. Aronson's.

Scheiring & Glatz.

CASTRATION UNDER COCAINE ANESTHESIA.

St. Louis, April 13, 1895.

To the Editor of the New York Medical Journal:

Sir: On January 17th of this year I performed complete castration for prostatic overgrowth (White's operation) on a man aged seventy-four, after the following manner: The parts having been properly asceptitized, the entire scrotal sac was seized by the left hand as high up as possible and manipulated for a sufficient time to relax the dartos and cremasters, after which a tolerably strong rubber band was passed above the hand about the root of the sac, close to the peno-scrotal and perineo-scrotal angles. This band was drawn tight enough to strangu-
late the scrotal and, probably, the funicular circulations. The line of incision on the anterior surface of each sac was now injected with a four-per-cent., sterilized solution of cocaine, four punctures being made and half a drachm of the solution used for each side. The needle was then inserted, half an inch below the constricting band, into the central part of the cords and five minutes of the same solution were thrown in. The scrotal punctures caused some pain, but the injection of the cords produced none. After the lapse of twelve minutes, pinching and puncturing the skin producing no sensation, the usual incisions were made exposing the glands and enough of the cords to answer the purpose, and the organs removed. The cords were ligated in toto, anchor loops were placed in the stumps and allowed to fall out of the lower angles of the incisions, and the wound was closed with continuous catgut sutures. The entire operation lasted twenty minutes. The band was now cut and the usual dressing applied.

So complete and satisfactory was the cocaine anesthesia that the patient was not aware of the steps of the operation, which was done at leisure, but conversed with a friend who was present at my invitation. When the testes were dragged upon for the purpose of ligating the cords above the points of puncture, only a slight sensation was felt, but the application of the ligatures was unnoticed. I think the cords were divided a trifle lower down than I have done when general anesthesia was employed, though the division could have been made at least an inch higher by the application of a little more force.

Beyond a slight mental exhilaration, no systemic effects of the cocaine were noticed. There was certainly no change in the respiration or the size of the pupil, and there was no flushing or paling of the face. The pulse remained as before the operation.

No published operation for castration done in an entirely similar manner has come under my observation. In fact, the use of the constricting band about the base of the scrotum, employed not as a haemostatic, but to imprison the cocaine in the scrotal tissues and to prevent its entrance into the general circulation, as has been so commonly done in other operations, notably in circumcision, was new to me; but it is quite possible that a record of such procedure may have been published in the voluminous literature that has followed the discovery and application of this drug, and I shall feel obliged to any one who will give me such reference, if there is any.

The patient, who had been under my care for over five years, had a weak and dilated heart, irregular pulse, more than a trace of albumin in the urine, and a mild cystitis of fourteen months' duration. Hyaline and slightly granular casts appeared in the urine in the fall of 1893. In January, 1894, he came into the hospital with a view of having suprapubic prostatectomy done, but his condition was even then such as to compel me to decline to interfere. The condition of the heart and kidneys seemed to me to contraindicate general anesthesia by chloroform or ether, and the general feeble condition led me to fear the effects of so severe an operation as prostato-myrectomy, an operation of the first magnitude, if my experience with twenty-eight cases is any guide. In the face of such conditions I hit upon the method described above, not daring to inject so much as three grains of cocaine without previously cutting off the circulation with the elastic band.

That one scrotal sac may be embraced in the elastic ligature, that the didymal tunica may be anesthetized with a smaller quantity of a weaker (two-per-cent.) solution of cocaine, and that the injection of the cord may be dispensed with, I have demonstrated by a phlebectomy for varicocele done on the 15th of January last. In this instance twenty minutes of a two-per-cent. cocaine solution, injected into the upper part of the left scrotal sac, previously strangled with the elastic band, enabled me to draw the cord through the buttock-hole, isolate and ligate the mass of veins, exsanguinate the stumps together, return the cord, and sew up the wound with but a trifling amount of pain.

I may be permitted to call attention here to a possible source of danger in cocaine anesthesia not usually noticed, one especially liable to occur when blood stasis is produced by a constricting band. The introduction of the cocaine solution under such a condition results in extensive coagulation of the blood, especially in the smaller veins. The two- and four-per-cent. solutions thus cause a true primitive red thrombosis. I have observed this in many cases of circumcision done with cocaine. So far as observed by me, this, often quite extensive, thrombosis does not interfere with the healing of the wounds. So long as these clots are aseptic no harm is likely to ensue; but a fault in the asepsis of the fluid, the syringe, the needle, or the skin over the field of operation might easily infect one or more of the thrombotic clots, which, getting about in the blood stream, would be capable of causing mischief at such a distance in time and location as to make it difficult to connect the consequences with their primary cause. Recent research seems to have demonstrated that cocaine inflicts a certain injury on the leucocytes, causing them to swell, become rigid, and cease to adhere to the vessel walls. May they not, in this condition, be the swift bearers of morbid agents to very distant parts? And may we not have remote effects of cocaine analgesia as well as of chloroform or ether narcosis? The advantage in the case of the cocaine lies in one's power to prevent such results by a most strict attention to asepsis.

In the most recent publication on the subject of cocaine in surgery (Local Anesthetics and Cocaine Analgesia, by T. H. Manley, A. M., M. D.; St. Louis: J. H. Chambers & Co., 1894) that has come to my notice, I find on page 157, under the enumeration of operations to which it may be applicable, the following: "For the treatment of spermatic varices; for the radical cure of hydrocele or all other operations on the scrotum or testes except, perhaps, castration." Nothing, however, is said of the use of the elastic strangulating ligature previous to injection. Surgeons accustomed to operate on prostates have come to regard the anesthetic as one of the chief dangers to this class of patients. Chloroform, so pregnant with immediate danger, has, in my observation, a remote danger but little less than that of ether. The possibility of lessening, perhaps even abolishing, this danger in the procedure proposed by White seemed to justify this communication.

sepsis and septic influences.
It was not safe to depend upon
malodorous discharges before determining the diagnosis. Treatment should be prompt and thorough, and should include
cleanliness, irrigation, and curettage.
Dr. F. W. Sears, of Syracuse, stated that it was important
that both obstetricians and nurses should be trained surgically
in view of the complications which were possible in midwifery.
The condition of the heart rather than the temperature was the
guide of importance in treating this disease. Mild cases would
usually end in recovery if the treatment was prompt and
thorough. Irrigation, if practiced at all, should be thorough
and persistent. It was useless if the septic elements had advanced beyond the uterus. In sucii cases the curette would be
equally useless, and in mild cases it was not especially indicated.
If gauze packing was used in the uterus it must be remembered
that it might act as a plug, shut in foul secretions, and make
matters worse.

With a patient already en-


feebled by the poisonous elements, the addition of the shock of so great an operation, even if it was done with skill and rapidity, must almost certainly be overpowering. Such patients were almost sure to die in any case, and as the result of unpleasant experience in this class of cases he had about concluded that abdominal operations should not be performed upon them. If the inflammation was localized and the purulent material could be readily evacuated without great disturbance of the abdominal viscera, the indication was equally clear to operate, and his experience with such cases had usually been satisfactory.

Dr. F. S. Low, of Pulaski, was opposed to all the methods of interference which had been advocated. Nearly fifty years of experience in country practice had taught him the truth of the maxim "meddleless midwifery is bad." He believed in giving Nature and natural forces a chance.

Shall Insane Criminals be Put to Death?—Dr. J. B. Ransom, of Danemora, read a paper with this title in which the question was answered in the negative.

Medical Examiners and Inquests in Cases of Death by Violence.—Dr. S. L. Dawes, of Saugerties, in a paper on this subject, maintained that an autopsy should be made only on those who were supposed to have died from violence, and in the presence of two or more witnesses.

The Curability of Cancer when the Lymph Nodes are Involved.—Dr. B. Farquhar Curtis, of New York, in a paper thus entitled, remarked that it was generally recognized that when the glandular system became extensively involved with malignant disease a complete cure by operative measures was impossible; hence the necessity of early diagnosis and operation. Infection of the glands with some forms of malignant disease—for example, sarcoma of bone—was of late occurrence, while with other forms, especially the carcinomata, it occurred relatively early. In carcinomata of the breast, though Gross had affirmed an average duration of fourteen months before the glands became infected, there were very many cases in which this occurred in a much shorter period, often before the disease had caused the patient sufficient trouble to warrant her in consulting a surgeon in regard to it. The track of the lymphatics from the breast to the axilla being in the pectoral fascia, it was evident that this should be removed in connection with the removal of the breast.

The Surgical Treatment of Empyema of the Antrum.—Dr. S. Lloyd, of New York, read a paper in which he said that this condition might result from disease of the nose or from curious teeth. If the teeth were removed while dental periodontitis was present, the diseased condition under consideration might result. Various methods existed of forming a diagnosis of antral empyema; for example, percussion, a stick being held in the mouth against the diseased part, also transillumination by means of an electric light in the mouth. It was important to determine that pus actually flowed from the opening in the antrum, and this was sometimes difficult. Most of the methods of treatment in use were defective. Schmidt's exploratory puncture, a hole being drilled between the two bicuspids, was very useful as a means of diagnosis. It was not always easy to get the pus out, even when its presence had been determined, especially if it was contained in compartments. The principle of draining from the most dependent point should be observed. The disadvantages of making a hole into the antrum through the alveolar process were, that a healthy tooth might be sacrificed in making the hole, the food might make its way through, and, if decomposition or caries was present, it was not easy to remove the offending material through such an opening. Desault's operation, by which a flap as large as a shaving was turned back from the gum, and a hole then chiseled into the antrum, gave plenty of room both for inspection and for removal of diseased and offending material. The objection to it was that infection might be carried to the mouth. The operation and the instruments recommended by Mikulicz were considered the best means of attacking the disease.

Dr. W. C. Phillips, of New York, thought that disease of the antrum was often overlooked, especially when it also involved the frontal and ethmoidal sinuses. Suppurative disease of the antrum was, however, relatively infrequent. He approved of transillumination as a means of diagnosis. Peroxide of hydrogen as an application he did not approve of, as it made a clot within the cavity which was difficult of removal. Spontaneous cure of the disease sometimes resulted; hence surgical operations were not always indicated. Especially was this the case if sound teeth were to be sacrificed. A polyloid condition of the antrum often co existed with empyema, and Myles had devised instruments for its curettage. For drainage the use of tubes was objectionable; gauze was better and was less likely to prolong the infectious process. Cleansing and alternative fluids should be used in the irrigation of the cavity.

The Treatment of Ocular Bllennorhoea in the Newborn was the subject of a paper by Dr. W. F. Mittenkopf, of New York, who said that this disease was the cause of more blindness than any other disease. In spite of various preventive measures, the disease had not diminished to any considerable extent. A simple plan of treatment was much to be desired. It should be preventive and curative. Thoroughly antiseptic midwifery was a prerequisite, but outside of hospitals this was not always possible. Crédé's method of treatment was most effective and had saved thousands of eyes. At the Sloane Maternity this method was in use, and in four thousand three hundred deliveries bllennorhoea had never occurred. In three hundred and fifty confinement at Charity Hospital, Blackwell's Island, there had been but one case, and in that one Crédé's method had been omitted. The disease was especially common with the children of primipares, and was usually traceable to gonorrhoea in the man. When the disease was actually present, ideal treatment would call for constant attention with two nurses. The eversion of the eyelids, especially the upper one, where the disease was principally situated, was difficult and might be dangerous to the eyes of the attendant as well as to those of the child. The author's suggestion was to combine a drochnum of boric acid with nine drachms of vaseline, draw down the lower lid, and with a feather or brush gently smear the lid with the ointment. This would be quickly transferred to the entire conjunctival surface. This should be repeated every five minutes, then every ten minutes, finally every two or three hours, until a cure resulted. In cases in which the secretion was already purulent, when the case was first seen one or two drops of a one-per-cent. solution of nitrate of silver should be instilled into the upper conjunctival sac, and then a stronger solution if necessary. If the cornea resembled a piece of opaque glass the disease was in its worst form and the sight would be lost. If there were only small patches of corneal infiltration, atropine should be employed. If it was too late, and perforation occurred, eserinse should be instilled.

(To be continued.)

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of December 5, 1894.

The President, Dr. C. C. Barrows, in the Chair.

(Concluded from page 578.)

The Treatment of Typhoid Fever with Typhoid Thymus Extract.—Dr. Alexander Lambert read a paper with this title. (See page 594.)
Dr. John Winters Brannan said that it was very difficult to estimate the value of any new treatment in a disease of such variable form as typhoid fever. He had himself treated ten cases by this method, and in five of them the results had seemed quite marked. One of these cases had been seen at the Roosevelt Hospital in the service of Dr. William H. Draper. Treatment had been begun early in the disease—as soon as a positive diagnosis had been made. Half a gramme had been given on the first day, the next day one gramme, the third day two grammes, the fourth day four, and the fifth day five. The temperature had not been affected by the injections until the fifth day, when it had fallen quite rapidly and had reached the normal in twenty-four hours, and had remained there. All other symptoms had improved at the same time in the manner described by Dr. Lambert. The patient, who during the treatment had complained bitterly of the soreness caused by the injections, had been full of gratitude for the relief produced by them. Some ten days later a relapse had taken place, and the patient had begged to have the injections repeated. Unfortunately, the supply of thymus solution had been exhausted, and the ordinary treatment, including the use of baths, had been employed. Under this treatment the relapse, as shown by the chart, had lasted twelve days—fully twice as long as the primary attack. As relapses in typhoid fever were usually of shorter duration than the primary attack, the result in this case would seem to speak for the efficacy of the injections. The speaker had given every injection himself—some fifty in number in the ten cases—and had seen no harmful result, either local or general. In two cases, including the one described, temporary soreness had been caused by the larger doses, but nothing more.

It was often difficult in typhoid fever to determine the real stage of the disease. Dr. William H. Thomson, who had succeeded Dr. Draper in the service at the Roosevelt Hospital, had wished to see the treatment tried on a patient in the very beginning of the disease. Such a supposed case had therefore been selected, and the patient had been given an initial injection. On the following day the man, who had been rather a free drinker, had been attacked with delirium tremens, and had died thirty-six hours later. The autopsy had shown lesions indicating that the disease had been really in the third week, instead of in the first week, as had been supposed. This inability on our part to determine the exact stage of the disease was an important source of error in estimating the value of the treatment. In the treatment of diphtheria with antitoxine it had been proved that, unless the antitoxine was used before the fourth day of the disease, there was no result. The same reasoning would seem to indicate that the results of this so-called specific treatment of typhoid fever would depend very much upon the stage of the disease in which the treatment was begun.

In order to observe the effect of the injections, the speaker said he had hitherto omitted all other treatment in his cases. He should now, however, employ baths and other remedial measures at the same time with the thymus solution. Cold baths did not shorten the disease, but they served to make the patient more comfortable until the possible abortive action of the injections had been obtained.

Dr. W. T. Northrup said that two conclusions had been reached as a result of their observations at the Presbyterian Hospital—viz.: (1) that the injections were harmless, and (2) that, so far as eleven cases meant anything, they were valuable. The experiments had been carried on as scientifically as possible, and other treatment had been suspended during the use of the injections, so as not to confuse the results. In one of the patients whose charts had just been shown the temperature had reached the normal within three days, yet at the same time they had had in the hospital another patient undergoing the usual treatment who had had an equally good temperature chart. Moreover, about this time ten new patients with typhoid fever had been admitted, and, after a careful diagnosis had been made, they had been subjected to the same treatment; yet the temperatures in these cases had not yielded. This new treatment had in no way improved the pulse, but during the treatment the pulse had become decidedly worse, and while it was being tried the delirium had steadily increased. In another case, where there had seemed to be no question about the patient being in the fifth day of the disease, the extract had been given in large doses, but without any effect. There had been one case which might have been pronounced improved by the injections, one had been doubtful, and the remaining ones had seemed to be uninfluenced by the treatment.

Dr. J. P. Thorneley, house physician of the Presbyterian Hospital, said that the injections had been given deep in the muscles of the gluteal region under antiseptic precautions, and in no case had there been an abscess. The injections had been, however, quite painful, and sometimes there had been some redness following them. Most of the patients had been attacked with quite a severe bronchitis—more severe, apparently, than in the other case which had been subjected to the regular bath treatment.

Dr. Le Fevre said that it had seemed to him that the typhoid fevers this last fall had been peculiar in that they had begun with a continuous high temperature and with bronchitis as an early, prominent, and very persistent symptom. On the other hand, the temperature range had not been at all typical, even for such cases as were usually seen in New York City. He did not see that the lower points of these temperature charts had indicated any lower grade of fever.

Dr. W. N. Hubbard said that twenty-six cases had been reported with two deaths, which would seem to him to be about the average mortality in New York City at this time. The typhoid-thymus extract, which Dr. Lambert had thoroughly tried, did not seem to have given very encouraging results when compared with the cold-bath treatment. Brandt had treated two thousand cases, seen before the fifth day, without a single death. The mortality in this city was usually over ten per cent. He was glad to note that the cold-bath treatment was being so generally used in the hospitals, and with such good effect. He had found it exceedingly beneficial to give as an antiseptic the sulphonamide of zinc in doses of three grains.

Dr. Le Fevre said that there had been much discussion concerning the cold-bath treatment, particularly as regarded peritonitis. He would like to ask for an expression of opinion on this point from those who had employed the cold-bath treatment extensively. Should the baths be given when there was decided evidence of peritonitis?
marked, and that the eruption had been unusually prominent, whereas the splenic enlargement had not been so great as usual.

Dr. Le Fevre said this had been exactly his experience.

Dr. Lambert said that the idea of the originators of this treatment had been that the bacillus was acted upon so as to produce a modified poison, and so either bring about tolerance, or in some way an active immunity. He knew of no observations as to whether or not the typhoid germ was actually changed, but the tetanus germ he knew became modified in that they did not form spores when grown in typhus bouillon. These injections might protect the organism before the typhoid poison had had time to thoroughly depress and poison the general nervous system. This would seem to be true from recent observations in experimental typhoid-fever cases. In cases where patients had been uncomfortable, sponge baths had not been omitted, although the tub baths had been stopped. Whisky had also been given when it had seemed to be demanded. He felt that in Dr. Northrup's cases the dose of the extract had not been sufficiently great; it should have been increased to at least six or seven cubic centimetres. He had carried out the treatment with a view to determining whether or not the allegations which had been made for it by foreign observers could be substantiated. Some of the cases had certainly been absolutely unimproved by the injections, but in others it had really seemed to him that there had been a distinct improvement which had been fairly attributable to the treatment. In a number of cases the temperature had been of a distinctly lower grade after the third injection, and the general condition of these patients had been improved. In none of the patients so benefited had there been present the classical picture of the third week of typhoid fever. He hoped that it would be possible for him in the future to bring out some antitoxine treatment which would give still more satisfactory results.

Book Notices.

Dr. Mitchell in his introduction to this volume states that it is intended to assist untrained observers who, as members of hospital boards, are presumed to study results into which enter questions of cooking, dietetics, ventilation, medical and surgical cleanliness, and analogous subjects, but who are without experience in regard to what is well and what is ill done. To insure the widest criticism, this manual, while in manuscript, was submitted to Dr. J. M. Da Costa and Dr. J. William White, of Philadelphia, and Dr. Hurd, of Baltimore, was induced to associate himself with Dr. Billings in the preparation of a work upon which, as Dr. Mitchell says, an amount of care and thought has been bestowed that is out of proportion to the size of the volume. The book was prepared at the suggestion of Dr. Mitchell, who confidence commends it to all who are managers or trustees of hospitals or are in any way connected with hospital work, and who are not contented to assume an official name and remain ignorant of how honestly to fulfill the duties that should go with it.

A careful perusal of the book shows how carefully the author and his associates have performed their work. The directions are comprehensive and arranged according to the different bureaus of the institution. A very good form to be used by visitors while on inspection duty is appended.

The little volume deserves careful perusal by everybody associated with hospital administration, and the application of its instructions must prove beneficial to such institutions.

Myxoedema, Cretinism, and the Goitres, with some of their Relations. By Edward T. Blake, M. D., M. R. C. S., Life Associate, Sanitary Institute, Great Britain, etc. Bristol: John Wright & Co., 1894. Pp. xi–13 to 89. [Price, 3s. 6d.]

The author states that the burden of his book is the septic or infective nature of disease. He considers Graves' disease in women as "an autotoxins," most frequently caused by the absorption of purulent products, while in men the same products lead to the production of rheumatism. If these products abolish the functions of the thryoid gland, myxoedema results; if they invade the cerebral cortex in large quantity and abruptly, insanity, such as mania, or a nervous disease, such as epilepsy, is the consequence. If the invasion is more gradual and the poisons more diluted, chorac is the result.

These hypotheses, which the author advances as a provisional pathology, are not supported by any evidence he adduces, and the book, while containing some disconnected facts regarding the diseases mentioned in its title, can not be regarded as a fair exposition of our knowledge of those diseases.

These five lectures have been published in the Edinburgh Medical Journal and are now given to the profession in the form of a volume.

The facts are brought forward that overexertion of the areas of the brain which form the substrata of consciousness produces changes in anatomical and physiological relations shown by trains of physical and mental symptoms; that the primary change is congestive in character; and that secondary changes may be produced, resulting in impairment of the systems of connection, with resultant permanent insanity.

The author wisely states that to approach the treatment of insanity through the portal of psychology is hopeless. These abnormalities must first be attacked through the organ primarily affected, and the great essential is rest for the brain. How this rest is to be secured, the methods of treatment that are to be followed, can not be reviewed here, but we can say that these lectures are a timely and valuable contribution to the literature of insanity.

In this brochure the author maintains that pulmonary tuberculosis is curable at any time before destructive changes have advanced to a point beyond which the organism is incapable of sustaining life. He holds that no two cases of pulmonary tuberculosis should receive identical treatment solely because they are tubercular, and attention is directed to the fact that the Bacillus tuberculosis alone is an inefficient causative agent of the disease, for the reason that there must be a pre-existing condition that offers favorable influences for the development of the bacilli, that act only as foreign bodies.
The anatomical and physiological relations of the circulation are reviewed for the purpose of bringing forward the foundation of the superstructure, the idea that tuberculosis is a symptom of lymphatic disturbance or stasis.

The author considers, that, as in tuberculosis the venous blood is brighter than normal, it is an evidence that some constituent of the red blood corpuscles is not properly oxidized in the tissues, a fact implying the absence of an oxidizing element. As the blood contains phosphorus in an oxidizable form, and as oxygen has a great chemical affinity for phosphorus, it is not out of reason, the author thinks, to infer that in the condition known as tuberculosis there is a deficiency of oxidizable phosphorus.

An antipathy to fatty food is considered one of the most important symptoms of inipient tuberculosis.

The treatment advised is by irrigation of the stomach with hydrozone, 1 to 10 of water, and a glass of a hydrozone solution, 1 to 32, half an hour before meals; and Churchill's or Gardiner's syrup of the hypophosphites as chemical foods. The suggestions regarding diet, climate, and exercise are those usually prescribed.

This work is popularly written in order to adapt it to schools and general reading. Anatomy and physiology are considered only in their relation with hygiene, which the author defines as a science that gives health and contentment to all who follow its rules. The text is generously illustrated, and the book is well adapted to school use.

BOOKS, ETC., RECEIVED.

A COLOR-CARRIER FOR EXAMINATIONS OF THE VISUAL FIELDS.

By Hugh T. Patrick, M. D., Professor of Neurology in the Chicago Polyclinic, Consulting Neurologist to the Eastern Illinois Hospital for the Insane.

The accompanying cut represents what I have almost ventured to call a pocket perimeter, simply because it may frequently take the place of one. It is, in fact, only a color-carrier, the eye of the observer being the perimeter. The perimeters of Schweiger and Dana should, I think, be called "portable" rather than "pocket," as they are far too bulky to be habitually carried in the pocket. My own little device, which has been in constant use for about two years and a half, is made of
two slender pieces of hard rubber, two inches in length, joined
together at one end by a rivet, the other being expanded into a
disc half an inch in diameter. The discs are countersunk on
both sides, leaving only a narrow rim at the edge, and into these
depressions are cemented pieces of colored felt such as are used
with a perimeter. When the blades are fully opened we have a
black rod, nearly four inches over all, carrying on one end white
and blue, and on the other red and green. By sitting facing the
patient and bringing the carrier in from the periphery, imitating
the curve of a perimeter, the fields for white, blue, red, and
green may be very rapidly estimated. It takes but little prac-
tice to learn the normal fields. For record a perimeter is essen-
tial, but for bedside, dispensary, and rapid work anywhere this
simple device will be found extremely useful, and, I venture to
think, make perimetric examinations more frequent. The folded
instrument may be carried in a small pouch such as is used for
pocket knives, and it takes up no more room in the waistcoat
pocket than a folded dollar bill. It may be obtained of Truax,
Greene, & Co., of Chicago. The rims around the discs as de-
picted in the cut are wider than they should be.

VENETIAN BUILDING.

Miscellany.

The Physiological Action of the Extract of the Supra-
renal Capsules.—The Journal of Physiology for April pub-
lishes three papers on this general subject. The first, by Dr.
G. Oliver and Mr. E. A. Schafer, was read at a recent meeting
of the Physiological Society, of London. In this communi-
cation the authors referred to some earlier experiments showing
that when an extract, whether prepared with water, alcohol, or
glycerin, of the suprarenal bodies of the calf, sheep, or dog was
injected—even in very small quantities—into a vein in a dog or
a rabbit the following pronounced physiological effects were
produced in a few seconds: 1. Extreme contraction of the
arteries, which was shown to be of peripheral origin. 2. A
remarkable and rapid rise of the arterial blood-pressure, which
took place in spite of powerful cardiac inhibition, and became
further augmented when the vagi were cut. 3. Central vagus
stimulation, so pronounced that the auricles came to a complete
standstill for a time, although the ventricles continued to con-
tact, but with a slow, independent rhythm. 4. Great acceler-
ation and augmentation of the contraction of the auricles and
ventricles after section of the vagi—the auricular augmentation
being especially marked. 5. Respiration only slightly affected,
becoming shallower.

A large number of observations made on dogs, cats, and
rabbits since last March have confirmed these results, and en-
abled the authors to determine others. As in their earlier ex-
periments, watery decoctions of the glands were chiefly em-
ployed by them. The suprarenals experimented with were
derived from the calf, the sheep, the dog, the cat, the guinea-
pig, and man. The physiological results were exactly the same
wherever the source of the glands, except in two which were
taken from subjects of Addison's disease. The following effects
are given by the authors: 1. As a rule, when the intravenous
mode of administration was adopted, a definite small quantity
of the extract representing a known weight of the fresh gland
was injected. In exceptional instances, however, a continuous
flow of a five-per-cent. solution of the extract was employed.
In these instances the physiological effects were maintained
during the entire time the injection lasted, but without the de-
velopment of other apparent symptoms and without causing
death. In this way large doses of the extract were admin-
istered to the dog, thereby producing the most violent cardio-
vascular disturbance without causing a fatal result. 2. In a
former communication the inference as to the extreme contrac-
tion of the arteries from observations on the blood-pressure,
from the use of the limb plethysmograph, and from the arrest
of the flow of normal saline through the vessels of a frog caused
by the addition of a small quantity of suprarenal extract. Sev-
eral observations with the onomerometer have confirmed this
conclusion and have shown that it may be extended to the vessels
of the kidneys; for the tracings have shown a well-pronounced
reduction in volume of that organ during the suprarenal effect
on the circulation. 3. It has been observed that stimulation of
the depressor nerve does not produce the usual reduction of
the blood-pressure while the effects of the suprarenal injection
last; that is, if the depressor nerve in the rabbit is stimulated
at the height of the pressure caused by intravenous injection
of suprarenal, the usual fall of blood-pressure is not produced,
and no depressor result is to be obtained until the blood-pres-
Sure has returned to the normal or nearly so. The depressor
result reappears simultaneously with the Traube-Hering curves,
if these are seen at all in the tracing. 4. It has invariably
been found that the heart's action is remarkably accelerated
and augmented in the dog, the cat, and the rabbit after section
of the vagi. In view of this powerful stimulation of the heart
in mammals, it was rather surprising to find a comparatively
small effect produced by the extract on the frog's ventricle.
It was not found that solutions of less than one per cent. of
suprarenal extract in Ringer's circulating fluid would affect
the frog's ventricle with certainty, recording its pulsations in a
heart-plethysmograph. The following results, however, were
obtained with this and with stronger solutions—up to five per
cent.: Reduction of diastole, with consequent acceleration. 2.
The abolition of groups of contractions and the setting up of
continuous pulsation. 3. The arrest of the ventricle in systole.
As this extreme effect of the extract was not prevented or an-
tagonzied by potassium chloride, the conclusion was that it was
due to calcium salts in the extract; for Ringer has shown that
the calcium effect upon the contraction of the frog's ventricle
is counteracted by potassium. Moreover, the individual con-
tractions do not show the characteristic calcium effect. On
the contrary, each individual contraction remains normal, al-
though the acceleration produced by the drug may ultimately
be sufficient to prevent the completion of the diastole, and the
contractions may thereby be caused to run together. 5. The
paralyzing effect of the subcutaneous injection of the extract—
about one or two grains—in the frog has not been observed in
other animals experimented on in this way, except from lethal
doses in the rabbit. It has been observed, however, in dogs
subjected to intravenous injections of the extract, that when the
muscles were electrically stimulated through the nerve supply-
ing them, a modification of the normal contraction was appar-
et, the relaxation being delayed, as in the case of frog's muscle.
This effect, moreover, not only was observed while the supra-
renal rise of the blood-pressure was being recorded, but was
traceable for some time after that rise had passed away. It was
therefore inferred that the active material was probably taken
up by and remained for a time stored within the muscular tissues.

6. No definite effect was obtained upon the secretion of the submaxillary gland as the result of injecting suprarenal extract into the blood. The chorda tympani was not found to be any less active in promoting the secretion of the gland in an animal the blood-vessels of which were contracted by the extract. 7. It was found that when two extracts were prepared of equal strength—1 to 100 of normal saline—one of the cortex and the other of the medulla of the perfectly fresh gland, the intravenous injection of the former would not produce the characteristic cardio-vascular disturbance, while that of the latter in the same dose would induce it in a marked degree. It is, however, the authors say, somewhat difficult to prepare the cortical extract perfectly free from a trace of the medulla, so that it may happen that a comparatively large dose of cortical extract may produce a slight physiological effect; but not more than that of a much smaller portion of the medullary extract. The conclusion, therefore, is that the active principle of the extract is present in the medulla only, the effects obtained from the extract of cortex being small and inconsistent and probably to be explained by accidental contamination or post-mortem diffusion.

8. Experiments were made with suprarenales from three subjects—one in which the glands were healthy, and two others in which they were diseased (cases of Addison's disease). The healthy organs provided an extract of great physiological activity, whereas the diseased adrenals afforded one which gave a purely negative result. 9. In view of the oral administration of the extract as a remedy, it seemed desirable to ascertain whether percutaneous digestion impaired its active properties. A little of the watery extract of the gland was added to artificial gastric juice (pepsin + 0.2 per cent. of hydrochloric acid) and exposed to a temperature of 104° F. for twenty-four hours. The intravenous injection of a small quantity of this and of an equal portion of the same extract diluted at the time to the same extent with 0.2 per cent. of hydrochloric acid produced identical physiological effects. The injection of an equivalent amount of acid as a check experiment produced no effect. The authors, therefore, do not think it likely that stomachic digestion will seriously lessen the physiological properties of the extract. 10. Experiments were made with the view of ascertaining how the extract was eliminated or disposed of, and whether the active principle was destroyed in the blood. This seemed not improbable, as it was found that alkalis and oxidation destroyed the activity of the extract. It was observed, however, that when allowed to stand in freshly drawn blood with free exposure to the air, or with complete exclusion of air for twenty-four hours, the extract possessed the same activity as when preserved in exactly the same manner in normal saline. It was also ascertained that clamping the renal vessels or the suprarenales themselves did not prolong or perceptibly modify the duration of the effect produced on the blood pressure by the intravenous injection of the extract. As an altered contraction of the muscles was observed to persist after the subsidence of the cardio-vascular disturbance set up by the injection, it seemed probable that the active principle of the extract passed out of the blood into the muscles, and remained there for a time.

The authors have shown that in Addison's disease the adrenals may become totally devoid of the physiologically active material. If these bodies are to be regarded as eliminators of toxic materials rather than as producers of materials which are of definite physiological value, the toxic materials they should remove or destroy might be expected, in cases in which their function is in abeyance, to pass out by the kidneys. They have found, however, that an extract prepared from the urine in Addison's disease has precisely the same effect when injected into a vein as that of an extract prepared from normal urine. In fact, all the evidence they have lends them, says Dr. Oliver, to view the function of the suprarenal bodies—as secretory rather than destructive, and the secreting product as being in all probability of great physiological importance for maintaining the tonic effect of the muscular tissues in general, and especially of the heart and arteries.

The second article is by Dr. Moore, of the University College, London, On the Chemical Nature of a Physiologically Active Substance occurring in the Suprarenal Gland. He gives the following account of some experiments:

The first experiments were made with a glycerin extract of which one part was equivalent to one of the fresh glands. A portion of this extract was treated with ten times its volume of absolute alcohol, filtered from the resulting precipitate, and evaporated to a syrup at a temperature of 156° F. This residue was dissolved in normal saline, tested physiologically by venous injection, and found to be very active. The precipitate caused by the alcohol was also extracted with normal saline and the extract injected and found to be inactive. Boiling the original extract, or a solution prepared by treating it with alcohol as described above, did not destroy any of its active properties; also on subjecting it to the action of acids or alcohols for a few minutes, then neutralizing and injecting, the extract was found to be still active. But it was shown by subsequent experiments that boiling for three or four hours with water alone, or heating to 104° with even very dilute alcohols for a similar period, completely destroys the physiological activity of the substance, while heating to 104° for a like time with different acids, varying in strength up to ten per cent., left it quite untouched.

A water extract of the gland was prepared by mincing the glands, covering with water for a few hours, boiling for a few minutes, and then filtering. This filtrate was evaporated to dryness at a temperature of 158° and a brown-colored residue obtained, of a sticky, wax-like consistence when warm, becoming brittle on cooling, and very deliquescent. This residue was found to be very active. It was extracted with various organic solvents—viz., ether, chloroform, carbon bisulphide, anil alcohol, benzene, and ligroin, as well as with mixtures of these solvents, but the active principle was not dissolved by any of them. Repeated extraction with boiling absolute alcohol gave a brown-colored wax similar to the original residue; even in hot absolute alcohol this wax, which is impossible to dry completely, is very feebly soluble, and in a later experiment it was shown that the fresh glands dried at 104° and then, after several extractions with anhydrous ether, placed under absolute alcohol, had a mere trace of the active principle extracted from them even after several days standing. The water extract, boiled and filtered, was saturated with ammonium sulphate, which caused a scummy precipitate; the filtrate from this, diluted with its own volume of water, gave a strong effect, a check experiment showing that an equal amount of half-saturated ammonium sulphate solution had no such action. The precipitate caused by saturation was extracted, injected, and found to be inactive.

The water extract was distilled in a vacuum at a temperature between 122° and 140°, and the distillate was found to be inactive. The brown residue remaining was also distilled in vacuo and the portion coming over below 212° and that between 212° and 356° collected separately and tested, as well as an extract of the charred residue—all three were found inactive. The brown residue which solidifies and becomes semisolid between 140° and 170° chars rapidly when heated above 302°.

Some fresh glands were dried at 104°, then, after several extractions with ether, and after standing for some weeks under absolute alcohol, were extracted with a small quantity of distilled water, and the filtrate allowed to dialyze into distilled
water through parchment paper. The dialyze was strongly active.

This dialyze contains some substance possessed of a powerful reducing action. Such a substance has already been described as occurring in the gland by Vulpius, and his observations have been confirmed and extended by Vireohow, Arnold, and Krukenberg.

The solubilities of the active principle, says Mr. Moore, are exactly the same as those of this reducing agent. Experiments in which portions of the cortex and of the medulla were carefully separated and made into extracts, demonstrated that the active principle was also confined to the medulla. Heating with dilute alkalies destroyed the active substance, and it also oxidized the reducing agent. Oxidation of an active extract for a few minutes with peroxide of hydrogen developed a rose-red coloration and at the same time very materially weakened the physiological effects of the extract. These considerations, says the author, point to the fact that the active principle and the body giving these peculiar reactions are probably identical, and in all cases where extracts possessing active physiological properties were afterward tested chemically for this reducing agent, it was invariably found to be present, while in those cases in which no physiological effect was obtained the reducing agent was found absent by chemical tests.

The action of various precipitants was tried on the dialyzed extract. Pratinic chloride gave no precipitate. A small precipitate was obtained by the use of this reagent in an alcoholic extract, but, on decomposing it with sulphuric hydrogen, filtering, neutralizing, and injecting, no effect was obtained, and the original filtrate from the pratinic chloride, after removing the excess of that reagent, gave a strong effect. A similar result also, says Mr. Moore, was obtained with mercuric chloride. Potassio-mercuric iodide gave no precipitate. On adding phosphomolybdic acid, the solution turned green and a blue precipitate fell, both, he says, evidently due to the reduction of the reagent. Nitrate of silver gave a white precipitate which rapidly turned black from reduction, even when kept in the dark, and, on heating, a silver mirror was rapidly obtained. The various extracts, says the author, were found not to reduce Fehling's solution even after boiling with mineral acids, and yielded no crystalline product when heated with phenyl hydrazine.

On passing a solution of the brownish resin obtained by evaporating the water extract to dryness through animal charcoal, to decolorize it and obtain a purer product, a colorless filtrate was obtained, yielding on evaporation fern-shaped masses of crystals, but on testing a solution of these no physiological effects were observed, and the active principle could not be reobtained from the charcoal by boiling with water. On trying the effect of smaller quantities of charcoal it was found that the solution, instead of being decolorized, became more deeply colored. Probably, says the author, the active principle is first oxidized by the charcoal and afterward decolorized.

The results obtained up to the present time are briefly stated as follows:

The active principle is soluble in water and in dilute alcohol; its solubility decreases with the percentage of alcohol present until with absolute alcohol it is almost insoluble. It is insoluble in ether, chloroform, amyl alcohol, carbon bisulphide, benzene, or ligroin.

It is not attacked by acids nor by boiling for some minutes, but is destroyed by alkalies, by oxidizing agents, and by continued boiling.

It is not precipitated by excess of alcohol, by saturation with ammonium sulphate, by mercuric chloride, potassio-mercuric iodide, or tannic acid.

It does not reduce Fehling's solution alone or after boiling with mineral acids, and it does not form a crystalline compound with phenyl hydrazine.

It is not volatile, either alone or with water vapor. It dialyzes freely through parchment paper, and the highly active dialyze so obtained is completely free from proteins.

With regard to the proteins of the suprarenal capsules, Mr. D. N. Nabarro, also in the same journal, remarks that an investigation was started with the view of ascertaining the nature of the proteins derived from the suprarenal bodies. The materials employed for examination, he says, were the suprarenals of calves. They were extracted with a five-per-cent solution of manganese sulphate within twelve hours after death. The proteins obtained were, for the most part, of the nature of globulins and nucleo-albumins; in other words, they were, with one exception, precipitated by saturation with manganese sulphate. The temperatures of heat coagulation were 132°, 149°, and 167° F. One albumin was present in small amount, coagulating at 152° F. The proteid coagulating at 132° was a globulin. It left no trace of a residue on digestion with artificial gastric juice. That coagulating at 149° left a very small residue on digestion; and the proteid coagulating at 167° also left a very small residue.

The extract of the glands made with five per cent. of manganese sulphate gave on acidifying slightly with acetic acid a considerable coagulum at from 104° to 105° F. On repeating the experiment with a second extract, the precipitation began at a still lower temperature, about 95° C. On careful neutralization of the same extract, and on warming, a thick precipitate occurred at 104°. Whether this was a precipitation of a globulin or of a nucleo-albumin Mr. Nabarro says he is not at present able to assert definitely, but that it was probably of the nature of nucleo-albumin, he says, would appear from the fact that a considerable residue was left upon gastric digestion. No peptin or peptone was present in these glands.

The Third International Congress of Dermatology will be held in London on August 4, 5, 6, 7, and 8, 1896, under the presidency of Mr. Jonathan Hutchinson. Dr. George T. Jackson, of New York, the secretary for the United States, has sent us the following regulations for publication:

1. All duly qualified medical men, British or foreign, or others interested in science invited by the council, who shall have paid the fee of £1 sterling, and who shall have enrolled themselves, shall be members of the congress and entitled to the volume of Transactions.

2. The official languages of the congress shall be English, French, and German, but with the permission of the president, members may express themselves in the language with which they are most familiar.

3. The proceedings of the congress shall be embodied in a volume of Transactions, edited by the executive council.

4. Communications relative to membership, papers, or other matters connected with the congress should be addressed to the secretary-general, Dr. J. J. Pringle, 28 Lower Seymour Street, London, W., or to one of the foreign secretaries.

5. The fee for membership shall be payable in London, at or before the opening of the congress.

It will greatly facilitate the work of the executive council if the fee is forwarded as soon as possible after the 1st of May, 1896, to the treasurer, Mr. Malcolm Morris.

6. Members who are unable to attend the congress shall receive the volume of Transactions.

7. The subjects treated shall be of two orders:

(1) Those selected beforehand by the executive council and
introduced by gentlemen chosen for that purpose by the council.

(2) Those selected by individual members themselves.

8. Subjects selected for debate by the council shall take precedence over those selected by the members.

9. The sessions of the congress shall take place from eleven to one in the forenoon and from three to five in the afternoon of each day.

10. There shall be clinical demonstrations of patients every morning from nine to half-past ten, and every afternoon from two to three.

11. Members contributing papers must submit an abstract of them to the secretary-general on or before the 1st of May, 1896, which will be printed either in full or in part, and embodied in the general programme of the congress which will be distributed at its opening.

12. At every debate precedence will be given to gentlemen who have communicated beforehand their intention to take part in it.

13. No papers lasting more than twenty minutes will be permitted. Speeches will be strictly limited to ten minutes each. Manuscripts of the papers read must be left with the secretary-general before the end of the sitting. The executive council shall decide as to the entire or partial publication of such papers in the Transactions of the congress.

Astigmatism or Astignia?—In a letter from its Paris correspondent the Lancet prints the following: "In the current number of the Annales d'oculistique Dr. Georges Martin, of Bordeaux, publishes a suggestive article on the correct nomenclature of the above condition. He reminds us that Dr. Whewell, when he invented the word astigmatism, meant to describe a condition in which rays emitted by a luminous point and traversing an eye of which the cornea or the lens are refracted less in the vertical axis than in the other axis, and could not consequently be brought to a focus or point on the retina. But Dr. Martin contends that Whewell should have chosen for his purpose, not στρίγα, στρίγανος (which really means puncture), but στριγή, στρίγας, which signifies a mathematical point. He points out that the word stigmata is commonly employed to describe the wounds made in our Saviour's feet and hands by the nails of the cross. Before, however, bringing the new word astigia to the notice of the profession, Dr. Martin consulted two competent Hellenists—M. Ouvré, professor of the faculty of letters of Bordeaux, and M. Monnier, law professor at the same faculty and a well-known Greek scholar. Dr. Martin adduces, as a further reason for the adoption of the new term astigia (astigmatia), the fact that the innovation would justify the use of the current word astigmatometer, which should logically be written astigmatometer under the old nomenclature. My friend Dr. Bull, of Paris, to whom I am indebted for this information, tells me that Dr. Martin's view has met with such acceptance that he himself (Dr. Bull) and Dr. Javal and Dr. Parent intend to employ the word astigia to the exclusion of Whewell's term astigmatism, and that the official sanction of the next ophthalmological congress will be sought for the innovation."

The Illinois License to Practice.—We have received the following from Dr. Marie J. Merger, the secretary of the faculty of the Northwestern University Woman's Medical School:

At a meeting of the faculty of the Northwestern University Woman's Medical School the following resolutions were unanimously adopted and ordered to be placed before the Illinois State Board of Health:

Whereas, On three occasions within the past three years the Illinois State Board of Health has licensed to practice medicine in this State students who have not properly qualified themselves for such duties, and whose incompetence has compelled us to withhold the degree of doctor of medicine, and

Whereas, By common report we are informed that the State board has adopted a similar policy with reference to numerous other persons, therefore,

Resolved, By the faculty of the Northwestern University Woman's Medical School, that the State board be requested hereafter to make its examinations so rigid that persons incompetent to obtain the degree of doctor of medicine from first-class medical colleges cannot obtain a license to practice from the Illinois State Board of Health.

Resolved, That the State Board of Health be urged to do all in its power to secure a modification of the State law so that the privilege of examinations for license to practice in this State can only be obtained by graduates of recognized medical schools in good standing.

Resolved further, That in the interests of humanity and medical science we believe the State board should make its standard of qualifications as high as that of the best medical colleges in this country, and that it should do all in its power to aid and encourage the efforts of the profession and the people for thorough medical education and higher requirements of licensates and for the degree of doctor of medicine.

The Nu Sigma Nu Fraternity will hold its thirteenth biennial convention on June 3d, 4th, and 5th in Minneapolis, with its University of Minnesota brethren. The association has twelve chapters connected with different medical universities and a membership which includes more than a thousand prominent physicians. It originated at the University of Michigan, the parent chapter being at present at Ann Arbor. The object of the fraternity is the intellectual and moral advancement of medical practitioners and the elevation of the standard of the medical profession. The last convention was held during the progress of the World's Fair at Chicago, when the following grand officers were elected: President, Dr. John L. Irwin, of Detroit; vice-president, Dr. James T. Christison, of St. Paul; secretary, Dr. Thad. H. Walker, of Walkerville, Canada; treasurer, Dr. F. Garvey Stabbis, of Chicago; historian, Dr. Ran-sam J. Parker, of New York; guard, Dr. John H. Mareanly, of Cincinnati; Dr. W. J. Lyster, of Harper Hospital, Detroit, is acting as secretary in the absence of Dr. Walker, who is now in Europe.

Enemata in the Treatment of Diarrhea.—In an editorial article the Therapeutics Gazette says: "We believe that large rectal injections, or injections of sufficient size to wash out the sigmoid flexure and colon, are not sufficiently resorted to, particularly in those cases of diarrhea in which a catarrhal element is well marked. In these catarrhal cases it will generally be found that mixed with the watery portion of the discharge there is more or less mucus in strings or flakes, which indicates, as a rule, that a certain amount of the trouble, at least, is situated in the colon. While the rule is by no means an absolute one, the presence of large quantities of mucus indicates very strongly that the whole trouble is in the larger bowel. It is evident, therefore, that the use of drugs by the mouth is a very indirect way of influencing the diseased area, since the medica-
ment must pass through the esophagus, the stomach, the duodenum, and the small intestine before it arrives at the point where its therapeutic efficacy is to be developed. On the other hand, good results are attained if large crypters are given by means of a hydrostatic syringe elevated not more than eighteen inches or two feet above the rectum. Such treatment will frequently control the movements, limiting them to one or two in twenty-four hours, even if the fluid character of the stool remains unchanged. Various substances have been employed dissolved in the water to be injected. Some of them have not only a powerful local action, but, in addition, are capable on absorption of producing widespread influences throughout the body. Among these may be mentioned salicylic acid and its relatives, nitrate of silver, iodoform when given in oil emulsion, and some of the vegetable astringents. The substance which has always given the best results under these circumstances is the sulphocarbate of zinc in the proportion of ten to thirty grains to an injection amounting to from two to three quarts. In some instances the water should be tepid, in others it should be as hot as the bowel can stand, and in still others it should be quite cold, the temperature of the injection depending largely upon the acuteness of the inflammatory process and the sensations of the patient, for in the same way that an application of cold water is grateful to a sprained ankle of one individual, while another prefers hot water, so does one patient get comfort from cold injections and another from heated ones. If the water be cold, care should be taken that undue chilling of the body does not result in feeble persons, or if hot, on the other hand, that a mild degree of heat fever is not produced. The success of this treatment depends absolutely, in many instances, upon the gentleness and care with which the injection is given, and the water must be allowed to trickle into the bowel rather than to enter it with any force, for the three reasons, that (1) if force is used, the bowel immediately resists the injection and perhaps forces it out. (2) It becomes so irritable that further injections are impossible. (3) This condition of rectal irritability reflexly causes irritability of the entire intestinal tract in much the same way that rectal fever may cause diarrhoea, and as a consequence, the patient is worse than before the method was attempted. In those cases of chronic diarrhoea in which the patient is markedly emaciated and unable to digest much food, so that the condition of impaired nutrition is an important factor in preventing recovery, this method of treatment is to be highly recommended, and it is worthy of note that a small rectal injection, amounting to an ounce or two of iodoform and sweet-oil emulsion, in the proportion of five grains to the ounce, injected into the bowel after a large watery movement has passed away, will relieve any tendency to tenesmus and, by the absorption of a small amount of iodine, exercise a useful influence over the catarrhal process which underlies the symptom which we are treating.

The Distribution of Assimilated Iron Compounds, other than Hemoglobin and Hematin, in Animal and Vegetable Cells.—No. 345 of the Proceedings of the Royal Society contains an abstract of a communication by Mr. Macallum, of the University of Toronto, who remarks that he has endeavored to determine with perfected methods the distribution of assimilated iron compounds in cells of all classes.

The methods adopted, says the author, were such as prevented a confusion of the iron of inorganic and alimentary combinations with that of assimilated compounds. The reagent which proved to be of the greatest service was freshly prepared ammonium hydrogen sulphide made from a solution of ammonium of 0.96 specific gravity, and applied, mixed with glycerin, to the isolated cells. Sulphuric, hydrochloric, and nitric acids, dissolved in certain proportions in alcohol of ninety-five per cent, strength, were found to liberate the iron of assimilated compounds, but the results obtained with these acids were, in all cases where this was possible, checked by experiments with the sulphide reagent. The iron liberated was readily demonstrated in the form of ferrous sulphide or of the Prussian-blue compound.

The fact that the iron of coagulated haemoglobin is unaffected, he says, by ammonium hydrogen sulphide enables us to overcome the difficulties presented by the presence of that colouring matter in many animal forms. The iron of haematin is, however, liberated by that reagent, but the rapidity with which this is done, under the most ordinary conditions, may be employed to distinguish the iron so derived from that of other organic compounds. Whether chlorophyll contains iron as a constituent of its molecule is still a matter of dispute, he says, but the presence of that colouring matter in vegetable cells does not complicate the results, since in the hardening process, especially when alcohol is used, it may be entirely removed from vegetable tissues, which then, so far as the distribution of "masked" iron is concerned, give no evidence of anything different from what obtained in Monotropa uniflora and in Caryella rhizans multiforma—plumeraceous plants destitute of chlorophyll.

Some of the more important facts ascertained in the investigation are thus briefly stated:—1. Iron, firmly combined, is a constant constituent of animal and vegetable chromatin. Another compound, less rich in iron, is found in nucleoli. 2. The chromophorins substance in ferment-forming cells contain iron, and the cytoplasm of Protozoan organisms, which also probably secretes ferments, yields evidence of the presence of a firmly combined iron compound. 3. A firm compound of iron is present in the chromophasic substance of the cytoplasm of fungi. 4. Of the non-nucleated organisms, bacteria, owing to their minute size, have, with one exception, given little evidence of the presence of an organic iron compound; but in the Cyanophysics the chromophasic portions of the "central substance" contain iron, and iron may also be demonstrated in the peripheral granules formed of the so-called cyanophyin (Pulla).

A Complimentary Clinical Report.—Dr. Augustus C. Bernays, of the Marion Sims College of Medicine, of St. Louis, has issued a handsome pamphlet containing the reports of a number of important surgical cases in which he operated last November in the presence of many well-known physicians who were in St. Louis on their way to attend the meeting of the Mississippi Valley Medical Association. The report is published as a compliment to those gentlemen.

An Enormous Vesical Calculus.—At the last meeting of the Medical Association of Georgia, held in Savannah on the 17th, 18th, and 19th inst., Dr. W. S. Armstrong, of Atlanta, exhibited a calculus which he had removed from a young man by the suprapubic operation on December 4, 1894. The calculus weighed thirteen ounces and a half and was twelve inches in its greatest and nine inches and a quarter in its least circumference. This is believed to be the largest stone ever removed in this country, the next in size being one weighing nine ounces and a half removed by Dr. J. William White, of Philadelphia. Dr. Armstrong's patient made a good recovery and is now pursuing his occupation as a farmer.

A Correction.—Dr. R. H. Cunningham asks us to state that an error crept into his article as it was published in our last issue, on page 494. The formula for the alcohol-formalin mixture should have read: Equal parts of alcohol, formalin, and distilled water.
CREDULITY AND SKEPTICISM IN MODERN MEDICINE.

THE ANNIVERSARY ADDRESS
BEFORE THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.
BY GEORGE HENRY FOX, M.D.

Mr. Vice-President, Ladies, and Gentlemen: The student of human nature finds in every calling the same types of men. While education in general and professional training in particular may stamp the individual with habits of thought and peculiarities of manner, there are certain innate characteristics of his mind which assert themselves under all circumstances. These mental tendencies are divergent and lead individuals to opposing extremes of thought. In political affairs the conservative and the radical, under a variety of names, have always contended for supremacy by pulling in opposite directions. In theology a never-ending warfare has ever been waged between orthodoxy and heresy, and, though men have been influenced by various reasons in taking one side or the other in religious controversy, it is evident that one man is by nature a zealot as another is a latitudinarian.

In medicine the same mental tendencies are readily discovered. The progressives, including the majority of the younger members of the profession, are always eager to adopt that which is new and to move onward, even though they find it necessary often to retrace their steps. On the other hand, the conservatives or "fogies," who, by the way, are not always old, are as naturally inclined to content with things as they are, and to do precisely what their fathers did before them.

In the intellectual progress of the age, however, both of these elements are moving onward together. Some active spirits will always crowd into the bow of the boat, and strain their eager eyes to catch the first glimpse of the unknown land which lies before them. Others will be content to sit in the stern and gaze at the foam-flecked wake that marks their progress. But whatever position we occupy, and in whatever direction our faces are turned, the spirit of the age in which we have embarked is carrying us all to the same goal, and with the same speed. No man can escape being influenced by the prevailing thought of his generation, and, whether he be a leader or a follower, whether he be in the van or the rear of the column, he can not do otherwise than advance. In every sphere of intellectual activity we are constantly moving forward, and the very rear of the procession has reached a point to-day which was perhaps far beyond the vision of the leaders of a preceding generation.

In medicine these mental tendencies lead to credulity on the one hand and to skepticism on the other. Physicians of one type exhibit an unbounded reverence for tradition, and are prone to believe almost everything that is taught. Those of a different temperament show little respect for the opinions of their predecessors, and hesitate to pin their faith to whatever is beyond the pale of their limited experience.

From credulity no individual is wholly free. Even the most confirmed skeptic is apt to be credulous at times and in regard to certain subjects. This element of human nature, which leads us to accept statements of fact upon insufficient evidence, has flourished as the offspring of ignorance in every age. It has furnished material for many chapters in the history of medicine. It inspired the ancient belief in witchcraft and demoniacal possession, and prompted the oft-repeated search for the philosopher's stone and the elixir vitae. It exists to-day in as marked a degree as it did centuries ago, although its absurdities are by no means as patent to us as they will be to those who look back upon this age a century hence. Credulity pervades all professions and all classes of society, and from its baleful influence neither the physician nor his patient can wholly escape.

The credulity of patients is a matter of every-day observation on the part of the physician. It is sometimes amusing; often it is lamentable. In fact, there is nothing more disheartening to the educated physician than to find that, after he has spent time and money in qualifying himself to pass judgment upon a case, his opinion is considered of no more value than that which is perhaps offered gratis by some meddlesome and medallistic busybody. The physician may be proud of his learning and of his reputation, but he can not escape a feeling of deep humiliation when he finds that his learning and reputation are wholly unappreciated. When he learns that a patient who is shrewd and successful in business and intelligent as regards the ordinary affairs of life, and who has paid him liberally for his advice, has listened with eager ears to the criticism of every old woman in the neighborhood, and finally concluded to consult some ignoramus or clairvoyant, he can not help feeling a sense of personal injury. This credulity of the average patient is the bane of the honest and conscientious physician, while it is the food upon which the charlatan thrives. The fact that it is far easier to make most patients imagine that they are well, or rapidly getting well, than it is to cure them, places a temptation in the path of every physician, and the fact that those who are ill in mind or body, or who imagine that they are so, are the most gullible class of people to be found, leads some men of education to forget the honor of their calling, and to stoop to practices which must degrade them in their own estimation, however much it may increase their income. But, to the credit of the medical profession, it may be asserted that the great majority of its members are proof against this strong temptation to practice upon the credulity of the public. Though well aware of the increased remuneration which such a course would insure, they are far more anxious to retain the respect of their medical brethren, and ever ready to sacrifice the opportunity of making money in order to uphold the honor and the dignity of their high calling.

Credulity on the part of the public has always been a drag upon the progress of medical science. It is the chief obstacle to higher medical education. While science has
always been cultivated for its own sake by a chosen few, the character of the medical profession has ever been determined in accordance with the law of supply and demand. In every age and in every land the average doctor has invariably been the style of practitioner which the people have desired. In the days when a belief in sorcery and astrology prevailed, the doctor naturally resorted to incantations, and sought for prognostic signs in the motions of the stars. Among savage tribes, who are imbued with the idea that sickness is due to the possession of an evil spirit, we find the medicine man beating a gong and seeking by other such means to frighten away the demon. It is only in communities where medical science is appreciated at its true value that physicians are willing to devote long years of study to a thorough preparation for the practice of their art. At the present day and in our own land the high position to which the medical profession has attained is largely due to the general appreciation on the part of the public that learning and experience constitute the basis of medical skill. The people demand that those to whom they confide their lives shall be men of education, thoroughly trained to accept the responsibility placed upon them, and the resulting is that, in the State of New York at least, no man who is not so qualified can practice for a day with impunity. But, so long as there remain some people of alleged intelligence, who are prone to a belief in miracles and faith cures, whose natural bent is toward mysticism and the alluring vagaries of pseudo-science, is it to be wondered at that more or less charlatanry is sometimes mingled with the practice of medicine? So long as patients like to be humbugged, there will always be some physicians willing to perform the operation.

But credulity in medical matters is not entirely monopolized by our patients, nor is it to be found only among the laity. The medical profession is by no means free from this unfortunate tendency, and manifests it in a variety of ways. A most striking example is seen in the general belief in the efficacy of drugs under all circumstances and in the necessity of administering them whenever an occasion offers. The average physician seems thoroughly saturated with the notion that the writing of prescriptions is the chief end of the medical man. His patient may be weary and need rest, poorly nourished and in need of food, surfeited and in need of a restricted diet, overworked and requiring relaxation, or addicted to habits which need only to be checked or abandoned. In short, his patient may simply need, as do very many of our patients, nothing more nor less than a little judicious advice—advice which any man with common sense perhaps might give, and which the physician of all men should be most competent and most ready to give. But how few physicians under such circumstances can refrain from seizing pen and pad and scribbling off the inevitable routine formula in abbreviated Latin! With this may possibly be offered in an unimpressive manner a few words of advice; but it is the Latin prescription upon which the physician usually lays most stress, and for which he expects to collect his fee. The result is that the patient hies to the apothecary, forgetting on his way the good advice which he may or may not have received, and merely trying to remember whether it was a teaspoonful or a tablespoonful of the medicine that was to be taken, and whether it was before or after meals.

This perfunctory administration of drugs is one of the crying evils of the medical practice of the present day. The physician is too frequently imbued with the idea that it is not only his privilege but his professional duty to hand over to the patient a written prescription. In the minds of the laity the common belief prevails that disease can only be cured by drugs, and this belief is generally encouraged and often unfortunately shared by many of our profession. Indeed, it is the undue importance which the physician usually attaches to his Latin prescription which leads patients to believe that his advice is perhaps worth listening to but seldom worth following.

Most physicians of experience will readily agree that the majority of patients who consult them for chronic ailments are far more in need of judicious advice regarding their habits of life than they are in need of medicine. And yet how few of us ever make the advice more prominent than the medicine! Theoretically, the advice and the prescription may supplement each other and both do good. Practically, the written prescription is apt to do positive harm in many cases by diverting the patient's mind from the advice which is so essential for him to follow, and centering it upon the pharmacopoeial remedy. It is this unfortunate custom on the part of physicians of writing a prescription for each and every patient that fosters the popular belief that disease can only be cured by drugs, and does far more than anything else to increase the business of the patent-medicine vendors. It is this routine administration of drugs that is gradually shaking the faith of the public in the efficacy of orthodox medical treatment—lessening confidence in true medical science, and leading many people of intelligence to investigate the alleged virtues of Christian science, mental healing, electric appliances, and movement cures, or, forcing them to the conviction that they will do better under the care of the athletic trainer than in the hands of the average drug-prescribing doctor.

And now that the allusion to athletic training has been made, let me ask if it be not a fact that simple hygienic treatment is plainly indicated in many cases in which drugs are freely administered? Would not a large number of our patients with chronic disease be better off in the hands of a judicious trainer than under the care of a grave and reverend pharmacopoe who, in spite of his profound study and ample experience, has yet to learn that highest of all professional attainments, the art of harmonizing medical science with common sense? Doubtless there are many physicians who, if quietly asked this question, would not hesitate to answer "Yes," although they might not care to publish their opinion through fear that it would reflect discredit upon the profession. But if we believe that it is a common practice to administer drugs to patients who would be as well or better off without them, and to ignore the simpler and more effective, though less mysterious, methods of healing, the sooner the fact is generally recognized and frankly admitted the better it will be for the reputation of our profession. Delusions, such as
homeopathy, with its sugar-coated expectancy, and Christian science, with its ancient ideas glossed over with a modern psychological varnish, are not merely absurd whims that have sprung from ignorance or charlatantry. Far from it! They are the protests of many men and women of intelligence against medical error. They are protests against the slavish adherence to traditional methods of treating disease. They are protests against that fetich of modern medicine, the routine administration of drugs. Ill-founded and ridiculous as these modern substitutes for rational medicine may appear to us, we cannot afford to miss the lesson which their existence and widespread acceptance would teach us. If we fail to discover our faults and to amend them in due time, rest assured that they will be discovered and brought to our notice. Let us not wait until a humiliating lack of confidence on the part of the intelligent public arouses us to a keen sense of our shortcomings. Let us not cherish our mistakes until our honored profession, which should mold medical thought and lead the public to a higher appreciation of the great advancement made by medical science, realizes that its prestige is waning, and that it has fallen back to a position in the rear of public sentiment.

The credulity of physicians is also shown in the present craze for new remedies. The manufacturing chemists on both sides of the Atlantic seem to vie with each other in flooding the market with new chemical substances or old ones under a new and high-sounding name. These substances are always theoretically of value. Each one is submitted to one or more experts, who are possibly well paid for a favorable report as to its virtues in actual practice. Other physicians are readily found who, animated by an unbridled enthusiasm for anything which is new, are glad to be among the first to test the remedy, and who are seldom, if ever, inclined to damn it with faint praise. A few glowing accounts of its wonderful efficacy are published in pamphlet form and scattered broadcast for the information of the profession. The advertising pages of our medical journals dazzle the eye with the names of the new remedies in large, bold-faced type. The average physician, fearing to be considered behind the times, prescribes the new remedy on every occasion and to the great satisfaction of the manufacturer, if not to the benefit of his patients. But long before he can possibly arrive at any just conclusion as to its merits he finds that he is forced to discontinue its use in order to try some newer remedy which has taken its place.

A generation ago the United States Pharmacopoeia was known and respected by every educated physician in the land, and pharmacopoeial prescriptions were almost the only ones in vogue. To-day a large percentage of the profession are unaware of the existence of such a book. Pharmacopoeial prescriptions are the exception, and proprietary remedies of unknown composition are the rule. It is true that new remedies of great value have recently been introduced in medical practice, but it is also true that the majority of those which now flood the market and absorb the attention of many physicians are either worthless or of questionable merit. They are introduced and exten-
sively advertised, not for the sake of suffering humanity, but for the pecuniary gain to their enterprising originators. The result of this must necessarily be detrimental to medical practice. Whereas the physician of a generation ago was quite as familiar as the apothecary with the drugs which he prescribed, the physician of to-day is daily prescribing drugs which he himself has possibly never tasted, handled, nor seen. He is, moreover, led into laying aside the old, tried, and effective remedies, and misled into using certain new ones of the nature of which he is ignorant, and of the effect of which he is uncertain.

But with all the credulity that pertains to modern medicine there exists at the same time a considerable amount of skepticism. This manifests itself in different forms, and may be either prejudicial or beneficial to the advance of science. In so far as it fosters a bigoted opposition to every change in the existing order of things, and interferes with the impartial examination of all novel ideas, it is harmful. But that skepticism which is born of a desire for bringing the truth to light, which refuses to allow blind faith to usurp the place of reason, is in no wise a bar to medical progress. On the contrary, it has shaken the foundations of error in the past, and promises to emancipate us from many a delusion in the future. We are often confronted with the statement that we are living in a skeptical age. Let us be thankful for that tendency of mind which leads us to distinguish between shams and realities, and which demands that rigid investigation must ever be the antecedent of belief.

It is often asserted that with increase of experience in the treatment of disease physicians are prone to lose faith in medicine. And it is certain that the older a man grows the more inclined he becomes to use only a few remedies, the value of which he has repeatedly proved, and upon the action of which he can confidently depend. But this restriction in the number of his remedies is not necessarily the result of a lack of faith in medicine. It is rather the natural outcome of caution in accepting the careless assertions as to the value of drugs with which our medical literature has always been burdened. It is a loss of credulity rather than a lack of faith. A long and often a disappointing experience has taught him that where there are many remedies for one disease it is highly probable that all are of comparatively little value. He prefers to cling to one remedy the effect of which he can depend upon, and which he can use with benefit in many diseases. He has learned the sad truth that the enthusiastic therapist who is extolling the value of a new remedy to-day is certain to be chanting in even a higher key the praises of some other remedy in the short space of a few months. This therapeutic skepticism, which is so often the outcome of age and experience, may be regarded as a balance wheel of medical progress, and can not be too strongly commended to the younger members of the profession.

There is no necessary connection between advancing years and loss of faith in medicine. We all know that some of the oldest and most honored of our profession are as enthusiastic in the acquisition of knowledge, as receptive of all new facts and theories, and as free from any suspi-

May 4, 1895.] FOX: CREDULITY AND SKEPTICISM IN MODERN MEDICINE.
The medical-journal writer *currente calamo* is quite as antecratic as the clergyman in his pulpit. The one writes, as the other speaks, with little or no fear of contradiction. The quiet occupant of the church pew is often compelled to listen to views with which he does not thoroughly agree, and to sweeping statements the truth or fairness of which he is strongly inclined to doubt. But all he can do is to sit in silence and wish that the other side of the question might be presented with equal zeal and ability. And so the reader of the medical journal, as he meets with assertions which do not tally with his own experience, or a line of reasoning which seems to him to be careless or illogical, becomes naturally impatient with the one-sided presentation of the subject which is forced upon him. He longs for an opportunity to have the writer of the article in a witness box and to subject him to a rigorous cross-examination. By such means he feels confident that the chaff might be separated from the wheat, and that in many cases the writer might be taught the valuable lesson that it is always a simple matter to assert, but often a difficult task to furnish proof.

It would certainly be an improvement in our medical journals if both sides, or various views of a question, were to be presented to the readers in the same issue. As is frequently demonstrated in our medical meetings, it is not the *ex-cathedra* deliverances of one mind, but the clashing of opinion in a free discussion, which proves to be the most entertaining and instructive. Possibly the medical journal of the future will constitute the chief forum for medical discussion, and publish no articles unattended by competent criticism. If so, it will seem more like the report of a medical debate, and less like a compilation of medical sermons.

There is one phase of skepticism in medicine which is the outgrowth of personal prejudice or national jealousy. It manifests itself in a belief that outside of a certain school, or sect, or nation, no scientific advancement can be made that is worthy of consideration, and that all ideas emanating from such a source are to be condemned without a hearing, and their upholders subjected to ridicule and persecution. This skepticism is the starting point of bigotry, and in many instances has fostered dissent and greatly impeded medical progress. As free thought and speech are cherished by us as inalienable rights pertaining to every citizen, so liberty of opinion on all medical questions is now conceded to be the birthright of every American physician. But in this free country our professions have not always coincided with our actions, and so far as the right of individual judgment is concerned there has been intolerance and bigotry in medicine as well as in religion. Our Puritan ancestors, who persecuted those who simply claimed the same freedom of thought for which they themselves had suffered, did not exhibit a unique phase of human nature. They bequeathed their spirit to many members of our profession, who in a past generation were quite as intolerant of homoeopathy and Thomsonianism, and quite as ready to persecute those whose medical opinions were not up to the standard of their self constituted orthodoxy. It is largely due to their narrow bigotry and
to their ill-advised attempts to stamp out medical heresy that sectionalism exists in our profession to-day—a sectionalism which reflects discredit upon science, and which hampers our best efforts in behalf of humanity—a sectionalism which we no longer regard with indignation, but which we most heartily deplore, and which is destined, as we both hope and believe, to lessen, and eventually to disappear.

But in spite of credulity and skepticism, and even the bigotry from which it must be confessed our profession is not yet entirely free, the status of the physician of to-day is immeasurably above what it was even a generation ago. The world has long been growing wiser and better, but now it seems as though we were advancing by bounds instead of by slow paces.

To appreciate fully what an intellectual revolution the past generation has produced it is only necessary to go back a few years to a period within the recollection of the older members of this society, and to compare the ideas which were then accepted in various fields of thought with those which prevail at the present day. In matters pertaining to theology, education, medicine, and other branches of speculative science the change which has taken place is a most startling and exceptional one; and, although it has been gradual and almost imperceptible, it is certainly as notable as the marked advancement which has been made along the lines of invention and discovery. Possibly our fathers and grandfathers were able to look backward and note a great change in their generations, but there can be no doubt that as regards intellectual advance the past generation has been the most remarkable in the world's history. The trend of thought for many successive years has been in a certain direction, and has finally culminated in the great change which has taken place in our lifetime. The views of thoughtful men and women have undergone a marvelous transformation during the past half century. In theological discussions strict dogmatism has lost its power. The fear of hell fire is no longer thundered from the pulpit as the main incentive to an upright life, and the belief that true religion conflicts with the established facts of science is gradually being surrendered. In educational affairs a much-needed reformation has been wrought. The schoolmaster's birch has become a mere tradition, and “the whining schoolboy creeping like a snail unwillingly to school” is utterly inconsistent with the prevalent idea of our day that learning should be made a pleasure and not a task. In medicine what a change has taken place! Leaving out of account the magnificent advances of modern medical science, what a change has taken place in the minds of the public respecting the function of the physician! The idea of combating disease solely by heroic measures has given place to the belief that the physician's first duty is to prevent disease, and the bleeding, blistering, physic-seeing doctor of forty years ago would seem sadly out of place in this day of hygienic sanitation and careful nursing.

But the achievements of the past, even those which have taken place within our own recollection, and of which we are in one sense a part, should not be made the subject of boasting. They are simply suggestions of our present ignorance, and intimations of those still greater achievements which are certain to follow in the years to come. As we look back and smile at the credulity of our predecessors, or wonder at their skepticism and intolerant opposition to views which now are firmly established, let us remember that human nature has not changed, and embrace the opportunity of beholding ourselves as we shall undoubtedly appear in the eyes of our successors.

Original Communications.

SOME THERAPEUTIC EXPERIENCES WITH THYROID FEEDING.*

By Leo Stieglitz, M.D.,

NEUROLOGIST TO MOUNT SINAI HOSPITAL DISPENSARY,
AND INSTRUCTOR IN NEUROLOGY IN THE NEW YORK PATHOLOGICAL.

Ever since the study of myxedema and its thyroid treatment showed to what an extent the thyroid gland controls the trophic condition of the skin and influences the nervous system, it has been tried in an experimental way in a number of other cutaneous and nervous diseases. Thus Braunwell,† Davies,‡ a number of other English authors, and more recently Crary,§ in this city, tried it in psoriasis, curing six cases out of seventy-seven—not a very encouraging result. It has also been used with some success in cases of ichthyosis, scleroderma, and chronic eczema; without success in lichen planus and various other cutaneous diseases.

My own experience with thyroid dates from the summer of 1893. The very remarkable effect observed from its use in myxedema upon the growth of the hair and nails suggested to me its use in a case of peculiar disease of the latter, for which no local cause could be discovered.

Case I.—The patient, Dora D., aged twenty-two years, single, and a cook, first sought my advice September 4, 1893, in regard to the diseased condition of her nails. She did not remember when the trouble first began, but stated she had doctored it for it for over a year without any success.

The nails in which the disease is most advanced are of a brownish hue, as if mortified; they are rough, irregular, and misshapen; they are short and stunted, as if retarded in their growth. The disease, where less pronounced, involves only part of the nail in longitudinal section, the diseased part being brown and occasionally separated from the healthier part of the nail by a longitudinal split. The nails least affected are rough, brittle, and mottled in appearance.

The skin of the hands is rough to the touch and slightly puffy. The growth of hair on the head and other parts of the body is abundant. The skin of the face and body is not abnormal in any respect. The nails of the toes show the same diseased condition as those of the fingers. A careful examination

* Read before the Manhattan Medical and Surgical Society, December 29, 1894.
of the nervous system and of the various viscera revealed no disturbance of any kind.

The patient was put upon five grains of Parke, Davis, & Co.'s desiccated thyroids, once a day the first week, the second week twice a day, and subsequently three times a day. At no time were any ill effects from the use of the drug noticeable. In the latter part of October, four weeks after the commencement of the treatment, the patient began to shed her nails and some of her hair. By the end of December a set of new, well-developed, smooth, and shapely nails had replaced the old diseased ones. The skin of the hands became smooth and soft. The loss of hair was followed by a more luxuriant growth than had been present before. The patient was presented in this condition to the New York Society of German Physicians on February 23, 1894. She subsequently stopped taking thyroid for a few weeks, and her nails began to show signs of returning disease, which disappeared when the treatment was taken up again, five grains being given every day or two.

Case II.—Paula D., aged seventeen years, sister of the first patient, was brought to me by her sister on February 23, 1894. The nail of her right thumb is affected in the same way her sister's nails were; it is brown, rough, thickened, and stunted in its growth. The girl worked for a year and a half in a gold factory, where she often had to put her thumbs into a solution of ammonia. The last six months she has not been working. She has noticed the change in her right thumb nail for the last year; none of the other nails are affected in the least. The patient was presented to the New York Society of German Physicians before being put upon a thyroid preparation. The latter was administered in a five-grain dose once a day, the same preparation being used, and created so much nausea that the patient stopped the treatment after a few days. During the next nine months the condition of the nail remained unchanged, the nail not growing at all, according to the patient's statement. On December 5th she began taking Burroughs, Wellcome, & Co.'s five-grain thyroid tablets, one a day, and has continued doing so ever since, the tablets creating no disturbance of any kind. Within a few days the nail began to grow, and on December 23d it was already half renewed, the new part being somewhat uneven, but of proper color and consistence.

I am able to show you to-night the nail in this stage of repair. The contrast between the healthy and diseased portion is striking. Whereas the proximal half is healthy in color and consistence, though uneven, the distal half is brown, brittle, and stratified. If the treatment is continued I do not doubt that the nail will be entirely restored.

These two cases show that even in the absence of myxodema thyroid feeding stimulates the growth of nails to a remarkable degree.

Case III.—Mary X., aged thirty-three years, single. The patient was never seriously ill until the spring of 1891, when she was taken sick with the grippe. She suffered from fever, cough, and pains all over her body, and especially in her legs; both feet were swollen, the right more than the left one; the swelling was white and not painful. After recovering from the grippe she felt very weak for six or eight weeks. The swelling in her feet disappeared very slowly. About two months later she first noticed two reddish spots on the inner aspect of the right ankle, each about the size of a quarter. The spots itched considerably, so much so that she rubbed them with a brush until they bled. They gradually grew larger, turning a dirty yellow color. At the same time the disease spread up the leg, involving the area of skin corresponding to the distribution of the internal saphenous vein.

The patient, who was kindly referred to me by Dr. Fleiner, of Heidelberg, was first seen on September 21, 1893.

Present Condition.—She is a large, well-developed woman; her skin is soft and pliable all over the body, except in the affected area of the right leg. The left leg is perfectly normal. The skin of the inner aspect of the lower leg from the ankle to the knee is thickened and of a dirty yellow tinge; it is shiny, and feels like leather to the touch. At the ankle it is glued to the bone; the diseased skin can not be raised in a fold, and is distended of all hair. About an inch above the knee there is a reddish-blue spot of the size of a five-cent piece; the skin at this point does not appear thickened, but is decidedly so to the touch. Another smaller spot of the same character is present about two inches farther up. These two spots present the disease in its first stage. The skin immediately adjacent to the thickened area on the lower leg is distinctly oedematous. Tactile sensibility is slightly diminished over the entire diseased area; otherwise no neurotic disturbance of any kind can be found. The thyroid gland can be felt, and does not seem to be altered in any way.

The diagnosis of seleroderma circumscriptum was readily made, as the changes were very characteristic. The patient had been taking arsenic for some time, but without any sign of improvement. As the condition of the skin resembled in some respects that found in myxodema confined to a small area, I put her upon desiccated thyroid gland (Parke, Davis, & Co.), five grains from one to three times a day; at the same time strychnine and fracture-stroplianti were administered, and electricity was applied to the leg. By November 1st the skin on the calf of the leg was somewhat more pliable; otherwise there was no change. The treatment was stopped for three weeks and then taken up again—five grains three times a day being administered—and was kept up, with occasional intervals of a week or ten days, up to October of the present year—i.e., twelve months. During this time the oedema along the tibia disappeared, the skin became more and more pliable and soft, and a new growth of hair appeared in the diseased area. The improvement set in in the most recently affected part—i.e., in the two spots above the knee and the area immediately below the knee, and was least marked about the ankle, the primary seat of the lesion.

On February 23d the patient was presented to the New York Society of German Physicians in a greatly improved condition. This improvement has continued without interruption. The patient was last seen on the 29th of this month, and with the exception of a slightly thickened patch immediately above the ankle the skin of the diseased area is soft and pliable as that of the other leg; it can now be raised in small folds from the ankle. The only sign of the disease left is a tawny discoloration of the skin, which is deepened immediately before menstruation.

It is not maintained that seleroderma can be cured by thyroid feeding. The change for the better and ultimate recovery may have been coincident with the thyroid treatment without having been due to the latter, as seleroderma, like alopecia areata, after running its course for some time has been known to take a change for the better and gradually disappear without any apparent cause. Nevertheless, the fact that immediately prior to the commencement of the treatment the disease had been steadily progressive and that improvement set in with the treatment does seem to indicate a causal connection between the two.
Muscular spasm in hemiatrophy of the face is not so very uncommon. I find it observed in the cases of Buzzard, Ziemssen-Wettc, Wolff, Eunninghaus, and Muratow, among others.

A full comprehension of the morbid processes in the stomach, of the symptoms of disturbed gastric digestion, can not be obtained without considering the relations between the stomach and the diseases of the other organs of the body; for every affection of the stomach is reflected back on the other organs, and inversely every disease of the organs reacts upon the stomach.

It is chiefly circulatory disturbances that lead to symptoms of congestion and its sequels which predominate in the morbid picture in diseases of the heart, the lungs, and the liver.

All diseases of the heart, whether of the valves, the heart muscle, or the pericardium, are sooner or later followed by the same result—namely, that, owing to the inevitable circulatory disturbance, the blood pressure sinks in the arterial system while it rises in the veins, which empty their blood with difficulty into the heart. In this way symptoms of congestion appear, which manifest themselves in all the organs of the body, and hence also in the stomach. These symptoms of congestion may be absent, as a rule, for a certain length of time in valvular disease, owing to the compensatory activity of the heart. It is only when this compensation is insufficient from the start or becomes defective in the course of the disease that passive dilatation of the heart ensues and is followed by the above-named circulatory disturbances and their sequels.

With reference to the circulatory disturbances in chronic diseases of the lungs, the diastole will no longer be sufficient, owing to the difficult inspiration, the afflux to the heart will be reduced, and therefore congestion must result. For instance, in emphysema, owing to the decreased pulmonary elasticity, the minor circulation is interfered with and the pressure in the pulmonary artery is increased by the destruction of numerous capillary regions. The blood pressure falls in the arterial distribution, the flow is retarded in the pulmonary circulation, and the final result is a slowing of the blood current in the latter; furthermore, there is stagnation in the veins of the major circulation and a retardation of the flow in the capillary regions.

In phthisis, in chronic pneumonias, and in the chronic forms of bronchitis circulatory disturbances are likewise caused by the permanent insufficient respiration. The restricted inspiration, with the resulting slower aspiration of the blood into the lungs and the heart, form the causal factors in the manifestation of the circulatory disturbances, which in later stages extend also to the major circulation.

As is well known, every prolonged congestion first leads to increased fullness of the vascular plexus in the affected region and a congestive translusion takes place;
the overloading of the parenchyma with products of metabolism is bound to exert a most pernicious influence upon the functions of the parts and upon their future nutrition. The accumulation of the transudate leads also to mechanical nutritive disturbances of the tissues, and, if these conditions persist for a longer period of time, to connective-tissue proliferation (induration); finally, the parenchyma may undergo atrophy. But the progress from congestion to induration and its sequelae is slow, inasmuch as compensatory processes come into activity. The first of these may develop locally, since, owing to the peculiar arrangement of the capillaries of the stomach, congestion can not be easily established. And even if the process has advanced one step farther toward the deleterious results of congestion, there are various ways in which the obstructions can be overcome by natural means.

Thus it is by no means uncommon in certain gastric affections associated with hyperchlorhydria—i.e., those in which the carbohydrates are digested with difficulty or not at all, and cause symptoms of irritation of the gastric mucosa by their prolonged presence in the stomach and their fermentation, and are moreover accompanied by unfavorable results from their weight—that increased motility comes in action, which insures a timely or even more rapid removal of the ingesta.

In a few cases, as a matter of fact, nothing remains of the three important functions of the stomach—secretion, motility, and absorption—but motility, and even in such cases the patients may continue comparatively well so long as this important compensatory power is preserved so as to propel the food in time and completely into the intestine. In that event, judging from some well-marked examples, the intestinal secretions are quite capable of effecting the digestion of the food, at least for a time.

Among the diseases of the heart it is the lesions of the mitral valve which lead earlier and more readily than those of the aortic to venous congestions in the stomach when the compensation is disturbed, and, as the secretory activity of the gastric mucosa is reduced, to chronic catarrhs. But it should be noted that disturbances of the function of the stomach may occur even though the patients are clinically in the stage of sufficient compensation.

Congestions in the stomach occur at an early period of the heart disease, and the patients often complain of acid eructations and a sensation of fullness after eating rather than of the heart, which is the cause of the symptoms.

Hufier never found free hydrochloric acid in patients with heart disease.

Adler and Stein, however, among twenty patients with heart disease found hydrochloric acid constantly in sixteen, occasionally in two, and absent in two. They explain Hufier's results by his mode of examination. They trace the gastric troubles of patients with heart disease to central causes. It is true, chronic congestion can likewise lead to catarrhs, and in this way, in an indirect manner, to a diminution of the secretory activity of the gastric glands.

Besides, a more marked interference with the venous reflux, such as occurs in pronounced compensation of the heart, will be followed by a restriction of the specific cellular activity, particularly with regard to hydrochloric acid.

Summarizing my own results briefly, I can only say that heart diseases per se have no influence upon the elaboration of hydrochloric acid. My findings varied between complete absence, inconstant presence of hydrochloric acid, and hyperchlorhydria—that is to say, in accordance with the prevailing condition of the gastric mucosa and the different other influences to which the secretion of hydrochloric acid is subject.

Owing to the congestion and the insufficient nutrition of the muscular elements in heart disease, we find the stomach not rarely in an atonic condition. Before entering upon the connection between gastric affections and diseases of the lungs, I should like to say a few words regarding the influence exerted by certain diseases of the nose upon the course of the functions of the stomach. The results of my investigations made with muco-purulent masses of a purulent rhinitis showed that the digestive power of an active gastric juice was weakened after the addition of such nasal secretion. Therefore disturbances of the chemical power, especially when the secretory activity of the gastric mucosa has been previously weakened, are apt to be temporarily caused in this manner, the small amounts of hydrochloric acid being neutralized. In the febrile and paroximal forms of rhinitis the patients swallow frequently, especially during the night, owing to the dryness of the throat, and drink repeatedly; thus the putrid masses are likely to reach the stomach and give rise to a direct or indirect inflammation of the gastric mucosa. In such cases I also found muco-purulent masses contained in the rinsing fluid from the empty stomach, which could only be derived from the secretion of the associated rhinitis.

Fenwick, to whom we are indebted for more accurate patho-anatomical examinations of the stomach in phthisical patients, reports the following results of twenty-five cases: Stomach normal in six; slight interstitial inflammation in nine; round-cell infiltration of slight extent in four; amyloid degeneration of the stomach wall in one; fatty metamorphosis of all the gland tubes in four. But, according to Schwalbe, there is no constant relation between the dyspeptic disturbances possibly occurring during life and the patho-anatomical alterations of the mucosa.

Ewald states: "This much only might be considered certain, that the subjective complaints of the patients are not always substantiated by the degree of the objective findings, and that it depends entirely upon the extent of the anatomical or functional disturbance present in a concrete case how far it will affect the secretion of hydrochloric acid."

As a matter of special importance I wish to point out that in a number of cases the symptoms of dyspepsia may precede the first manifest signs of phthisis; this is the reason why, in spite of prolonged treatment of the gastric troubles, little effect is not rarely obtained, until some day the true cause of the phenomenon becomes apparent. These dyspeptic troubles already indicate the expression, the effect, of the venous hyperemia and congestion as a result of the disturbed pulmonary circulation.
However, the functions of the stomach in one and the same patient are so variable that no general rule can be laid down; thus it often happened to me that I found in the examination of one patient no free hydrochloric acid, while two or three weeks later, without anything being done, nearly normal quantities of hydrochloric acid were present (Ewald).

In the initial stage of phthisis Klemperer found normal secretion and weakened motility; in pronounced phthisis, hydrochloric acid inconstant and hyperacidity; in the terminal stage, diminished secretion and dilatation of the stomach. The findings show nothing characteristic and are merely the signs of subacute and chronic gastritis. The cases of hyperacidity may be explained in the following manner: The great stimulation caused by the prolonged presence of food in the stomach produces more abundant glandular secretion; but the same stimulus to which the glands respond by increased secretion induces an interglandular cell proliferation in the mucosa, which again restricts the secretory activity. Finally, the anatomical alteration of the mucosa progresses, the glands cease to secrete, and anacidity occurs. The dyspepsia of phthisis, therefore, runs its course in the manner of a chronic catarrh beginning with motor weakness, secretion being normal; then follows a stage of hyperacidity; finally the secretion is arrested and dilatation sets in.

O. Rosenbach calls attention to the fact among others that sometimes, even in grave cases of phthisis, especially when slowly progressive, no digestive disturbances are found.

Hildebrand found that the absence of hydrochloric acid coincided with the higher temperatures.

In diseases of the liver, likewise circulatory disturbances—that is to say, in the distribution of the portal vein—and their deleterious influences on the function of the stomach play the most important part. On the other hand, there is often so intimate a connection between liver and stomach that not rarely we find it difficult to decide which condition is primary and which secondary. Thus, for instance, in profound digestive disturbances of the stomach there is contamination with the products of imperfect digestion of the blood in the portal vein, and as a result a retardation of the hepatic circulation, which in its turn must manifest its injurious effects on the stomach.

Cirrhosis of the liver we often find, as a result of the restricted portal circulation, hemorrhages into the gastric mucosa which may give rise to the development of gastric ulcers. Such hemorrhages, however, need not necessarily cause typical ulcers, inasmuch as the hemorrhages may be parenchymatous and not circumscribed lesions of the mucosa, and in the mean time these processes, owing to the catarrhal condition of the mucosa, may produce diminution of the acidity so that the requisite disproportion between blood and gastric juice is lacking as a factor in the production of an ulcer.

With reference to the connection between the kidneys and affections of the stomach, Fenwick, in his oft-quoted paper, has furnished us the best information. Chronic diseases of the kidneys form the chief causes of chronic gastritis. In Bright’s disease the incapacity of the kidney to perform its function in the proper manner seems to be the direct cause of the gastric disturbance. After injecting urea Fenwick found it in the contents of the stomach and in the alcoholic extract of the mucosa; from this he concludes that the gastric mucosa excretes certain poisons, urea, etc.; but that, as a result of the irritation induced by the process of elimination, an inflammation of the gastric glands occurs. Leube considers the dyspeptic symptoms in contracted kidney as a manifestation of uremia in general of a nervous origin.

Bernacki found the gastric secretion diminished in nephritis; the hydrochloric acid more or less decreased, not rarely altogether absent; often there was a total lack of pepsin. The further investigations of the same author show: 1. That during the presence of oliguria and edema the diminution of hydrochloric acid is more pronounced than after the restoration of the urinary secretion and the disappearance of the edema; as the quantity of urine increased, so did the hydrochloric acid. 2. That when the edema is more marked, when more albumin is excreted, and when the secretion of urine is lessened, the quantity of free hydrochloric acid is diminished proportionately.

Atonic conditions of the stomach are not often found in chronic diseases of the kidney, but very frequently an accelerated propulsion of the stomach contents into the intestine canal (hyperkinesis). This increased gastric activity was found not only in quite recent but also in older cases, and at the same time hydrochloric acid might be present or not. This hyperkinesis explains why the food does not stagnate and give rise to catarrhs, and why the patients do not show the slightest subjective disturbance of the stomach despite the marked anomalies of the gastric secretion.

Incidentally I shall make mention of the pretended causation of a dilatation of the stomach by the pressure of the right wandering kidney upon the pylorus and the fixed portion of the duodenum, which is asserted to hinder the passage of the food from the stomach. I can recall two cases of my own in which there was a right wandering kidney associated with gastropathy—in c., displacement of the entire stomach in toto—without dilatation.

In diseases of the intestines it is the obstruction of the portal circulation through the liver, during which congestion occurs in the entire fundamental distribution of this vessel, which is sure to manifest its injurious effects upon the stomach likewise.

According to Rosenbach, constipation—which, indeed, is frequently merely a consequence of gastric dyspepsia, because the digestive disturbances within the stomach in some manner weaken the peristaltic movements of the intestine—when marked or chronic in character, in turn gives rise to considerable dyspeptic troubles which apparently spring from the stomach, since it prevents the expulsion of the ingesta into the intestine, which is distended with feces or gases. Of course, both constipation and gastric dyspepsia may represent co-ordinated conditions which develop simultaneously as a result of a general atony of the digestive tract (for instance, in anemia). Ewald
speaks of a case of typical gastrectasia without any demonstrable cause, developed after many years of obstinate constipation, which would lead one to suppose that the persistent sluggishness or paresis of the intestine may give rise to diminished peristalsis of the stomach. In this connection I may mention the disagreeable stomach troubles which manifest themselves by anorexia, pressure or pain in the gastric region of persons suffering from obstinate constipation, often lasting many days, which condition changes into a feeling of well-being after this constipation is overcome. I am inclined to look upon this as an irritation produced by the firmer contents through mechanical pressure upon the fibers of the sympathetic and vagus, unless we prefer to ascribe it to the simultaneously developed phenomena.

I shall dispose with a few words of the connection of gastric affections with some diseases of the genital organs.

Of the various neuroses associated with retroflexion of the uterus and dependent upon it, the gastric neurosis is probably the most frequent. Often, however, we may observe the persistence of the gastric neurosis in spite of the cure of the retroflexion. Quite recently, indeed, clinical investigators have devoted increased attention to the digestive disturbances which are not due to an organic disease of the digestive apparatus but are based upon certain conditions of irritation or atony of the nervous system. Every gynaecologist will admit that women suffering for a long time from sexual diseases complain chiefly of gastric disturbances of a widely varying nature associated with them. In such cases we have to deal with dyspeptic disturbances without organic alterations of the digestive apparatus, in which the diseases of the uterus and its annexae give rise to centro-petal irritations of the nervous system which in a reflex way act upon the digestion. Thus we often meet with gastralgias of the most violent kind with the onset of menstruation; in these cases there may be increased or continuous acid secretion which ceases after the flow.

I shall conclude with the digestive disturbances observed during or after general diseases.

How important it is to follow the rule of examining the urine of every patient is proved especially by diabetics, in which the dyspeptic troubles are often regarded as a disease per se until the sugar is accidentally discovered in the urine.

According to Leube, gastric digestion in diabetic patients is normal despite the greatly increased quantity of ingesta; in rare cases we may observe the development either of atony of the stomach or of permanent gastrectasia.

Rosenstein found in diabetes:
1. In a number of cases free hydrochloric acid is lacking for a longer or shorter period of time, and this absence is to be looked upon as the expression of a gastric neurosis.
2. Extensive atrophies of the gastric mucosa in consequence of an interstitial gastritis.
3. Where free hydrochloric acid is constantly absent the cause is to be ascribed to an atrophy of the glandular apparatus caused by an interstitial inflammation.

In anaemia and chlorosis, owing to the defective blood supply, the activity of the gastric glands suffers likewise; in the majority of cases of this disease we have to deal with a diminution of the hydrochloric acid. Still, there are exceptions to the rule: even in the gravest forms of anaemia, in the so-called pernicious anaemia, the acidity is by no means always diminished, according to Leube.

In chlorosis I frequently found atomic conditions of the stomach and not rarely pronounced dilatation; also a diminution in hydrochloric acid.

It is well known, too, that in consequence of the insufficient nutrition due to the deteriorated quality of the blood (possibly fatty degeneration of the vessel walls) there may occasionally be spontaneous haemorrhages into the stomach. Equally well known is the fact that the large majority of gastric ulcers occur in chlorotic girls about the period of puberty.

Finally, as regards the gastric disturbances occurring in connection with malaria, no systematic investigations are to be found in the literature, to the best of my knowledge. I have collected fifteen cases of so-called masked malaria and made a careful examination of the secretory anomalies of the stomach.

Laveran, on November 23, 1880, first presented to the Academy of Medicine of Paris the communication that he had observed in the blood of patients suffering from the Algerian form of malaria peculiar protozooids organisms which do not occur in other diseases and most probably cause malaria. Since that time Laveran's investigations have been confirmed by many observers.

For my investigations I selected that form of malaria which we term masked (larvata)—a disease which is not rare here in New York, owing to the situation of the city and the frequent excavations in the streets, which expose the deeper layers of the earth and bring to the surface numerous vegetable substances to be acted upon by the sun. This disease rarely manifests itself in violent or typical pyrexial attacks, but rather by a feeling of lassitude, especially in the legs, and drowsiness at certain hours. Some patients complain of neuralgias of various kinds—cephalalgia, gastralgia, intercostal neuralgia, supra-orbital neuralgia, etc.; others again complain of palpitation, asthma, pain in the left side, and particularly violent pains in the legs, which are often edematous. With regard to the digestive organs the subjective symptoms show nothing characteristic: anorexia, fullness after eating, eructations, constipation. Objectively we not rarely find anaemic heart murmurs and irregular, often merely intermittent, hypokinetic heart action. The spleen, as a rule, is enlarged and can be palpated as a hard tumor. The stomach, being slightly sensitive, shows the following: Among the fifteen cases examined by me, the secretion of hydrochloric acid was diminished in nine; nearly the same number of cases showed atomic muscular weakness of the stomach walls; in one there was a remarkable untimely occurrence of lactic acid. In most cases the motility was reduced. The remaining six cases showed various inconstant findings. Plasmodia I could demonstrate in only four cases.

It will be good practice in cases where the dyspeptic
symptoms are more or less independent of the ingestion of food, show a certain regularity in their occurrence, and are absent at some hours of the day, to suspect the influence of malaria as the cause and to examine for plasmodia, or to prescribe tentatively large doses of quinine.

PERICHONDritis of the Laryngeal Cartilages.†

By C. P. AMBLER, M.D.,
CANTON, OHIO,
FORMERLY LARYNGOLOGIST AND RHINOLoGIST IN
THE VINTAII SANITARIUM FOR DISEASES OF THE LUNGS AND THROAT,
ASHVILLE, N. C.

Perichondritis of the laryngeal cartilages as a primary disease is a very rare affection, the condition, as it is usually found, being secondary to a morbid process in the perichondrium. It is not the purpose of this paper, however, to consider at length those cases due to tubercular or cancerous deposit, but rather to confine our paper to the subject in hand as a primary disease.

The etiology of this class of cases is always more or less obscure; we have it following any debilitating disease without any apparent cause, especially typhoid fever, pneumonia, and diphtheria. Bosworth (Diseases of the Throat and Nose) reports thirty-three cases collated by him, two having occurred in his own practice. Of these thirty-three, nine are, given as idiopathic, nine as syphilitic, eleven followed typhoid fever, one followed diphtheria, one was traumatic, and two were probably due to lorysosis.

Von Ziemssen (Cyclopedia of the Practice of Medicine, vol. vii) mentions a case caused by the frequent introduction of an esophageal bougie, the cricoid being the seat of the trouble.

As is usual in the more grave of our throat troubles, men are more often affected than women.

Thyroid involvement alone offers the best chance for recovery; the arytenoid cases are less fatal than the cricoid; but the cases where both the cricoid and the arytenoid are involved promise least of any, excepting, of course, where all the group are involved.

The perichondrium, being a firm fibrous membrane, is usually able to withstand the ordinary inflammations of this region; but when suppuration once begins beneath it, this same density prevents easy evacuation of the pus, and we have it burrowing along between the cartilage and its covering until, if evacuation is still retarded, the circulation of the cartilage is interfered with, necrosis of the cartilage supervenes, and, if the pus still does not find a vent, the cartilage may be entirely dissected loose.

When this stage is reached, the swelling has become very marked, greatly interfering with all the functions of the part. If spontaneous evacuation occurs, or if free incision into the pus cavity is made, the sequestrum may come away with the first rush of pus. It is seldom that this occurs, however, the cartilage usually coming away in pieces, and then only after weeks of continued suppuration.

If free and thorough evacuation of all purulent material and necrotic tissue is made at once, the process of repair may be rapid. When the sequestrum or parts of the sequestrum remain behind, or when the necrosis has only affected one part of the cartilage, and the same is attached and intact throughout the remainder of its surface, then a profuse, long-continued suppuration sets in; the discharge is constant; cough becomes more troublesome, while the suffering from dyspnea and dysphagia is_lessened; the general health becomes impaired and further embarrasses the process of repair; if operative measures are not employed now, the necrotic tissue removed either through the lumen or by thyrotomy, the chances for recovery become very small.

Edema may suddenly arise, the proliferation of granulating connective tissue around the fistulous opening may become so extensive as to interfere with respiration, and in either case tracheotomy is the only procedure that will give relief; the perichondrium and adjacent structures undergo a bullous thickening, which seriously interferes with what motion remains in the articulations.

The functional disability, which is first and last a prominent symptom in all forms of this disease, involves phonation, deglutition, and respiration, more or less, according to the cartilage or cartilages affected.

It is not probable that laryngeal perichondritis, as such, is ever diagnosed in the beginning.

Pain, cough, hoarseness, lymphatic involvement, dyspnea, and dysphagia are so often seen as symptoms of more trivial affections of the throat, that, even did the laryngeal image differ, one is liable to be mistaken.

The early structural change under inspection has no distinctive pathognomonic appearance; indeed, after the presence of suppuration beneath the perichondrium, the laryngeal image, when taken alone, could not be differentiated from ordinary submucous abscess.

The history of the case, the external objective and subjective symptoms, together with careful laryngoscopic examination with a probe after the use of cocaine, may determine the exact state of affairs; but it is only where we have a well-advanced case, with thrown-off cartilage, or open fistula in which we can use a probe, that the absolute extent and true state can be determined.

The laryngeal image differs and varies greatly according to the cartilage and extent of destruction.

If the arytenoid cartilage alone is the seat of the disease, it gives rise to a unilateral tumor, pear shaped, and encroaching upon both air and food tracts. Deglutition is interfered with greatly on account of the improper closure of the glottis, pain, and swelling. Dyspnea is seldom an urgent symptom in this form, unless the tumor is accompanied by edema.

The crico-arytenoid articulation becomes the seat of an effusion resulting in ankylosis, which abolishes the mobility of the cord upon that side. The voice becomes low and hoarse, but not necessarily lost.

The course of the disease in this is the same as in the other cartilages, except that, the fistulous opening once established, the final exfoliation occurs in a much shorter time.

† Read before the Canton Galen Club, Canton, Ohio, March 4, 1895.
I have a case of arytenoid perichondritis under observation at this time in which there has been no evagination. Whether the disease is tubercular or not remains to be seen. With the exception of this case I have never seen a case of arytenoid perichondritis which was not tubercular. In fact we are always suspicious of tuberculous deposit when the enlarged pear-shaped arytenoid is found.

Tuberculous ulcers upon the posterior wall of the larynx are especially liable to be associated with chondritis of the arytenoids. They are found most frequently as single ulcers upon the vocal process, anterior side of the arytenoid, and cartilage of Santorini, these ulcers penetrating the perichondrium and laying bare the cartilage. In contrast to their depth they are often very small in diameter and can be easily overlooked. As von Ziemssen says, "in making a post-mortem one needs a probe in order to demonstrate the necrosis of the cartilage."

If either arytenoid cartilage has been entirely necrosed and thrown off, the soft parts, with Santorini's cartilage (see cut), sink in, and if the infiltration following the inflammatory process is not too extensive, the median line of the larynx assumes a position near the diseased side.

The thyroid cartilage is much more abundantly supplied with blood-vessels than the other cartilages of this group, and hence a thyroid perichondritis is not so liable to result in such extensive destruction of tissue as is observed in the other cartilages. It is when the disease is met with in this cartilage that the external symptoms are most marked. The swelling obliterates the uniformity of the pommum Adami on one or both sides, and fluctuation may become apparent. If the abscess opens externally we may determine the extent of necrosis by the insertion of a probe.

In one case in my own practice (No. III) the abscess evidently burrowed downward, and opened immediately above the sterno-clavicular articulation, establishing a fistula which remained open for years. This case was not seen until the fistula was established.

In this case true laryngeal fistula was also present, as could be demonstrated with a probe in position, the same being easily seen in the laryngoscopic mirror. (See sketch, Case III.) Schrotter mentions a similar ease as occurring in his own practice (von Ziemssen, vol. viii).

Perichondritis of the cricoid cartilage occurs generally on the plate, and when occurring with tuberculous laryngitis will be found associated with arytenoid complications. The rule is for the arytenoid to become affected first, the crico-arytenoid articulation becomes involved, is either lost entirely or is ankylosed, and the morbid process begins in the cricoid.

The symptoms are similar to those mentioned as occurring in thyroid and arytenoid cases, but laryngeal stenosis in this form becomes most aggravated.

This is caused primarily by the protuberance of the abscess upon the posterior wall, which protuberance may in a few days reach such a degree as to cause alarming symptoms, and secondarily it is a favorite site for the proliferation of callous and connective-tissue granulations.

The vocal cord becomes displaced upon the affected side toward the median line, and this, together with destruction or paralysis of the posterior crico-arytenoid muscle, results in very marked dyspnea.

The ultimate result when all the cartilages are affected is death. In those cases where only one or possibly two of the cartilages are complicated the case runs a somewhat protracted course, with no special tendency toward a fatal termination other than the constant danger from laryngeal stenosis, in which tracheotomy may be required, and the gradual impairment of the general health.

The prognosis must always be guarded. The mildest case may extend notwithstanding all we can do, and the probable impairment to the voice should be explained.

The treatment of the acute stage of the disease requires active general and local antiphlogistic measures: ice pack externally, administration of pellets of ice, leeching or cupping, cocaine to larynx, cathartics, and, as Bosworth suggests, the early and continued use of iodide of potassium. Later the measures must be directed to the relief of the dyspnea, the management of the abscess and sequestrum, if any, and finally the relief of the resulting or threatened stenosis from cicatrix. When tracheotomy becomes necessary the high operation should be done in preference to the low, as this gives local bloodletting and furnishes an opening where possibly something may be done with the purulent accumulation or sequestrum.

The sequestrum should be removed as early as possible, as its presence undoubtedly stimulates the formation of connective tissue proliferation and increase of stenosis. The severing of adhesions by the intralaryngeal knife or dilator, the removal of proliferations or other obstructive formations by the double-cutting curette, snare, or galvanocautery, are indications for certain cases.

Without the laryngoscope we can do nothing.

In extensive cases the patience of the patients will become exhausted, and they go from one throat specialist to another without the desired relief until finally death gives them their release.

I must not close this paper without giving credit to the excellent articles upon the rare affection by von Ziemssen and Bosworth, from whose works I have freely quoted.

The following cases occurring in my own practice may be of interest:

Case I.—On March 12, 1894, John B., aged fourteen years, presented himself with a very small fistulous opening upon the pommum Adami. Three years before he had had typhoid fever, and this discharge was first noticed about six weeks after he was up and about. The fistula was situated in the center of a slightly raised nodule, was painful, slightly inflamed, would close for a day or two and then break out again. Had never been much better, and, if any change during past year, was a little worse. Discharge was muco-purulent. No intralaryngeal morbid process could be demonstrated. All kinds of applications had been made, and he had undergone one operation without benefit.

Probing with a delicate probe proved the fistula to be of thyroid origin. We decided to operate. On March 20th, assisted by Dr. Marchand, we dissected down, and found, as supposed, that the fistula did spring from the thyroid cartilage. In fact it appeared to come directly through it. The opening
was extremely small, and evidently the necrotic condition was on the other side, with this fistula leading through the cartilage. The fistula appeared to end at a point corresponding with the perichondrium of the inner side—at least we could not follow it. Fearing the result of extending our operative measures would be worse than the original trouble, we closed the wound, removing an elliptical piece down to the perichondrium. Twelve days following the fistula again opened through the site of our wound, discharged about a- before, and settled down to business again. We next cauterized the base thoroughly, and again with no result. He now drifted out of my hands, and I next heard of him being under treatment of one of his quack competitors, who guaranteed to cure him. That was eight months ago, and I occasionally meet him on the street yet with a bandage around his neck.

This was comparatively a trifling case, and yet demonstrates how important it is to get at the seat of the disease.

Case II.—Mrs. K., of Washington, D. C., consulted me October 27, 1894, having been troubled three years with extreme hoarseness, and at times complete aphonia. Has occasionally suffered with pain over larynx ever since trouble began. Cough was troublesome, but not constantly so until four months ago. Coughed almost constantly since, except when under an opiate. Expectorated considerable heavy material a year ago, and has been expectorating since cough became so bad.

Delegation but slightly interfered with. No dyspnea if she keeps quiet; marked upon exertion. Lost sixteen pounds in weight; feels weak; no fever. Pulse always above 85, average 90. Had complete aphonia a year and a half ago which lasted six months. This cleared up suddenly after expectorating considerable purulent material, "in which were noticed small pieces of tough, flat tissue," evidently cartilage. Has been unable to articulate now for six months. Has at several different times suffered from dyspnea.

By laryngoscopic examination find granular pharyngitis, marked thickening of the right arytenoid (see sketch a, Case II), right vocal cord crowded to median line, the cord being congested and swollen. Left arytenoid showed evidence of suppuration with elimination of part or whole of the cartilage, the soft parts being sunk in, leaving a marked depression. This evidently was the point from which suppuration had occurred a year ago, and after the rupture of which abscess she regained her voice.

She had been treated for "nervous cough," "bronchitis," "catarrh," and other equally indefinite diseases, without benefit.

The larynx was so distorted and the chink of the glottis so much encroached upon that no view could be had of the sub-vocal region. No fluctuation could at that time be demonstrated. She was put upon treatment as outlined above and the arytenoid closely watched. At the end of a month fluctuation was apparent (see sketch b, Case II), and the abscess was opened with the intralaryngeal knife. This gave immediate relief from the slight dyspnea which had been present; the cough changed in character and ceased to be so distressing. No necrosed cartilage came away.

Her voice now improved, and some days she could speak quite distinctly. The swelling gradually subsided, and with it the distortion of the larynx, allowing a better view of the subglottic region. No nodular process found there.

The last time I saw her—February 29 (see sketch c, Case II)—the fistula was still open, the discharge being very slight; still a watery, purulent accumulation. She coughed but little, slept well, gained in weight, and on the 5th returned to Washington. She was greatly improved, according to her own statement, but, of course, it is probable that the necrotic change going on then will before long assume some new phase and again require attention. A radical operation might be best, but in her present comfortable condition she will not listen to it. It will eventually kill her.

Case III.—Ray A., Canton, aged eight years, June 6, 1894. This case was brought to me on account of a fistulous opening immediately above the left sterno-clavicular articulation. When two years of age he had suffered with a severe attack of diphtheria. Is a large, well-developed boy, very bright, but has never been able to articulate so that he could be understood except by his mother. Fistulous opening of about the size of a pinhead, and situated in center of raised indurated ring. A small flexible whalebone bougie could be easily inserted five inches always following the same course and leading directly to the cricoid cartilage. About half a drachm of purulent watery fluid could be proc- ed out. The father stated that the opening had established itself about three months after he recovered from the diphtheria, and had discharged every day or two since. When it first opened it discharged very freely for a few weeks. No suspicion had ever been entertained that there was any connection between this opening and his laryngeal difficulty. Repeated attempts had to be made before any satisfactory view of the larynx could be obtained. The epiglottis pointed to the left instead of perpendicular, and the whole larynx seemed twisted in that direction. But one cord could be seen—the right—this looking normal in color and size. The neck being fat it was difficult to outline the parts, but the left cricoid appeared sunken in and the resiliency was lacking. One interesting point was that the probe could be seen in the larynx when in position through the fistula (see sketch, Case III). Nothing was attempted in this case. The boy was well, strong and fat.
coughed but little, and surgical interference might only make matters worse. I was unable to satisfy myself whether his in-

ability to articulate was due to structural change in the larynx or to paresis. The crico-thyroid muscle on the left side was evidently affected, and how many more I could not say. He could make plenty of noise with the larynx, and I am inclined to believe that the inability to adjust the parts was due to loss of structure.

Case IV.—Mrs. McK., Bowerston, Ohio, aged fifty-four years, consulted me on July 31, 1894. Very hoarse for three months; dyspnea upon exertion; no dysphagia; coughs but little; temperature normal; pulse, 124. Thinks she "had night sweats" a year ago, and had some fever about the same time every day. No tubercular history in family. Been treated for "catarrh of the windpipe" without any relief. Present weight, one hundred and twenty-two pounds; former weight, one hundred and forty pounds. Feels weak, and has a sense of oppression or fear of something, knows not what. Can not speak above a whisper, and it is tiresome to do even that. External swelling marked over right side of larynx. Tender upon pressure over cricoid cartilage.

The right arytenoid was enlarged and inflamed (see sketch 1, Case IV), right cord greatly swollen, and could not be outlined from the false band. The whole right side of the larynx appeared raised up, and the left correspondingly depressed. Below the cords appeared a large, rough mass, which filled up about half the chink of the glottis. Under a probe this was firm and unyielding, while fluctuation was found in the right arytenoid. The left side of the larynx was not affected. On August 9th, after repeatedly manipulating the larynx with the probe, the larynx was cacedined and the abscess opened. The

voice improved but little. The galvano-cautery was applied to the mass below the cords with considerable benefit. I saw her constantly until September 20th. The swelling subsided over the arytenoid, the small fistula remained open, she breathed better, the voice was stronger, she gained in weight, and was better in every way. On December 7th (see sketch 2, Case IV) she returned, still feeling very well, except that her voice was very hoarse. She could, however, talk out loud. She returned this time to see if something could be done for the voice. The mass of granulation tissue immediately below the right cord was evidently the cause of this hoarseness, and I advised an intra-

laryngeal operation. On December 7th I removed the greater part of this mass with Krause's double-cutting punch. At two subsequent sittings the remainder was removed. (See sketch 3, Case IV.)

While questioning her this time I found her throat trouble dated back several years instead of three months. The proliferation removed was evidently a product from a former suppuration. I gave my opinion, at first, that the case was tubercular, but since opening the abscess and getting tissue away I have repeatedly examined for tubercle bacilli and found none.

She returned home a few days after the last operation, coughed considerably, but gradually improved.

On February 14th I was called to Bowerston to see her. She had had a slight attack of grippe, and was afraid she was going to have trouble in breathing.

She was better when I got there, and said she had been able to talk with her neighbor across the street ten days before, and as she could not do so now she wanted me to see her. I found the throat in comparatively good shape, and since hear that she is all right again. (See sketch 3, Case IV.)
Here is a case where the very worst was threatened: where no hope was given either patient or husband; where we thought tracheotomy might be necessary any day, and by intralaryngeal operation she has regained her voice, coughs very little, sleeps all night, eats easily, has increased in weight from one hundred and twenty-two to one hundred and forty-eight pounds, is comfortable, and evidently has several years to live yet. I do not allege a cure, but am glad I can report the best results in my worst case.

**ELECTRICITY IN MEDICINE**

FROM A MODERN STANDPOINT.*

By William James Morton, M. D.,

Professor of Electrotherapeutics

And of the Diseases of the Mind and Nervous System

At the New York Post-Graduate Medical School and Hospital.

(Concluded from page 472.)

**Electrotherapeutics.**

The brief time of ten minutes allotted to the reading of papers before you necessarily confines my presentation of this branch of our subject within narrow limits.

He who would appeal to electricity as a therapeutic aid in medicine should build upon broad principles and not upon narrow ones. Two such principles occur to me:

1. The broadest one which I am able to formulate, and which I would in fact suggest for a definition of electrotherapeutics, in a biologic sense, is that electric energy applied to the vital energy of living organisms undergoes a transformation into the energies characteristic of such organisms; the energy termed vital is modified by the energy known as electrical; it is a question of electrical energy versus biological energy. Of the vital energy we may say that its beginnings are life; its normal progress is health; its perversions are disease; its cessation is death. At some point in this gradient, either as a somatic aggregate or as a cellular unit, the applied electric energy of electrotherapeutics is transformed into some form of vital energy—namely, transformed into some function of protoplasm and its modifications.

The transformation is into chemical energy when electrolysis is effected, into mechanical energy when tissue elements are distorted or strained or when cataphoresis is established, into neural energy when the nerve elements are excited, into muscular energy when the muscle is caused to contract, into secretory and excretory energy when glands and other organs are excited, and into nutritional energy when, by aid probably of the trophic nerves, the tissue combustions are accelerated. The fundamental definition of electrotherapeutics may then be said to be the transformation, by the law of conservation of energies, of electric energy into the energy peculiar to individual vital cells.

2. A second broad principle is that electricity, to be worked with successfully, must be regarded not as an entity, like a drug, but from the standpoint of a consider-

* Contribution to discussion before the Medical Society of the State of New York at its eighty-ninth annual meeting.
such experiments were not conclusive until the polarity of the magnets should be rapidly alternated.

4. Induction Effects.—These, no doubt, take place in the use of alternating currents like the faradistic. With currents of high frequency and high potential such currents render lamps put in the circuit of the patient's body incandescent. They, of course, are of the same nature as the inducing current, and only serve to spread the original effect over greater areas of tissue.

5. Electrolysis is the most important property of the constant or galvanic current. It takes place only at the expense of the tissue, which undergoes a chemical decomposition whether the current strength be great or little. If the current strength be sufficient to cause an actual and final disruption of the atoms of molecules, which, as oxygen and hydrogen and various subsidiary chemical products—acids and alkalies—collect at the electrodes (generally metallic needles), we have an instance of visible, polar, or surgical electrolysis. If the molecules are not disrupted we have the ordinary medical electrolysis.

As an electrolyte, the human body may be regarded as a two-per-cent. solution of common salt, and since current conduction is due to the salts of the body held in solution and constituting, though in small amount, a most essential element of tissue, it is plain, aside from laboratory and clinical experience, that from a physical point of view alone electrolysis profoundly alters tissue constituents and structure. Even a few milliampères of current conducted electrolytically by the solutions of inorganic salts, decomposing and diminishing them in amount, may produce profound effects, for the function of the tissue depends upon its physical integrity, and it is its physical integrity which suffers by the passage of the current. This action probably explains the effect of electricity in setting up a retrograde change in the growth of many tumors, especially fibroids in their early stages, and is also one reason for the absorption of inflammatory exudates wherever their locality.

In connection with these views it must be always borne in mind that the modern view of electrolysis holds that its activity is existent at every part of the circuit and not alone in the polar regions.

In general, I regard the property of electrolysis as one which must be employed with great discrimination and caution. Illustrative of this position, I may cite an experiment by G. Weiss, who submitted one leg of a healthy frog to a few milliampères of current for several minutes and placed the frog back in the aquarium. At the end of a week the frog's legs were tested to determine their relative excitability. The leg not submitted to the currents was from ten to twenty times more easily excited than the electrolyzed leg. This latter leg was amputated, and upon microscopical examination it was revealed that marked structural changes had been produced in the muscle fibers. Experiments of this nature demonstrate that the continuous current reduces nerve and muscle excitability by setting up structural changes.

The question at once arises, In what class of cases do we desire this effect?

In spinal-cord diseases, in neuritis, and in all instances where regeneration of nerve and muscle tissue, or, indeed, of any tissue, or the resumption of functional integrity is to be promoted, I believe that the galvanic current, as commonly employed—namely, strong currents—retards recovery.

My only reservation in making this statement is that if we knew which pole to use it is possible that the case may turn out to be different, for there is some reason to believe, as has been pointed out in the section upon electrophysiology, that the negative pole may retard destructive and retrograde and catabolic events in tissue, while the positive pole may accelerate them. This view is still sub judicex.

Certain it is that there is a growing feeling in favor of the use of mild (one to five milliampères) galvanic currents in the class of cases alluded to, where reparation and not retrogression is desired.

On the other hand, retardation of the excitability and of the growth of tissue and reabsorption of exudates may be desired. This I believe to be the practical function of the electrolytic or galvanic current, and especially of the negative pole of this current. As a result of long experience, I have learned and have taught for many years that the negative pole is emphatically the right pole and the best treatment to apply in all cases of chronic inflammation so called—that is to say, in all cases where from causes like traumaism, infectious processes, rheumatism, and so forth, a hyperplasia of connective tissue and an impaired local nutrition exist. In such cases, be the resulting chronic inflammatory process within the pelvis, within organs, in joints, nervous structure, muscles, or skin, wherever newly formed fibrous tissue may have located itself, the negative pole, and it alone, exerts what may be termed a reabsorptive action.

Under this action I have seen a youth's neck, twisted inflexibly to one side and held there by exudates succeeding to operation and septicism, become perfectly normal; have seen the contents of female pelvis, rigid from similar exudates, soften and become movable; have seen chronic joints, fixed by fibrous ankylosis, resume their flexibility, and in cases without number witnessed the resolution and absorption effects of the negative pole.

I will say further, as a matter of personal opinion, that the negative pole is nearly always indicated, and that, with but few exceptions, I should regulate the positive pole to the position of the indifferent or dispersing electrode.

In this connection I will pass about for inspection a delicate metallic cloth which may be cut into bandages, etc., and wrapped about joints or uneven surfaces upon the top of absorbent cotton or sponges or toweling, thus greatly facilitating the even distribution of current.

6. Cataphoresis.—Cataphoresis means the movement of fluids in tissue by the directive action of the constant current; this movement is, in general, from the positive and toward and to the negative pole. When the fluid to be moved is a solution of some medicine, applied, as a rule, to the positive pole and forming electrolytic continuity with skin, mucous membrane, or deeper tissues, I have termed the procedure cataphoric medication.
Cataphoresis, the movement of the fluids of tissues, is an inevitable associate with electrolysis. By it fluids accumulate at the region of the negative pole and abandon the positive pole. Thus, the negative pole is said to be a "wet" and the positive pole a "dry" pole; the action at the negative is "liquefying," at the positive pole desiccating. These distinctions are exemplified in a striking manner in the Apostoli treatments, where the positive pole is used to combat hemorrhagic conditions, the negative to promote retrogression and absorption. This action is most marked in the use of bare electrodes, like needles and sounds, but is not absent in percutaneous treatments with sponge electrodes. It has an important bearing in promoting, by liquefaction, the absorption of fibrous tissue exudates.

Cataphoretic medication has opened out a vast and practical field of new work in electrotherapeutics. The medicine to be introduced through the skin of a patient may be in solution in a "galvanic bath"; the solution may be placed within the uterine, vaginal, rectal, buccal, or other cavities, within which at the same time is placed the positive electrode; it may be injected into tissue and diffused by a positive pole, needle, or cannula; it may be simply placed upon a piece of blotting paper with a flat carbon electrode of positive polarity resting upon it; in all instances, with a moderate flow of current, within a few moments medicines like iodide of potassium, iron, quinine, strychnine, mercury, and many others may be detected, upon examination, in the urine. Practical applications of this principle are the use of mercury in syphilis, of local remedies like iodide in goitre and other affections, of lithia salts in rheumatic joints, and perhaps the most practical of all, the production of a most reliable local anesthesia by means of a solution of hydrochloride of cocaine. There are few minor operations in surgery that I do not now perform under electro-coagulation local anesthesia.

Cataphoretic Medication from Soluble Electrodes; "Metallic Electrolysis."—The principle of electric diffusion, combined with the chemical decomposition of the electrode and of the tissue with which it is in contact, has furnished to us, only most recently, a new method of procedure, than which there are few more practical, more efficacious, and therefore more important, in the entire range of electrotherapeutics. I refer to a procedure inaugurated by Dr. Gaurier, of Paris, and commonly termed metallic electrolysis. Its essential feature is that an electrode, as, for instance, a needle, a sound, a probe, a bulb or any other, is manufactured out of a metal—say copper or zinc—which is vigorously attacked and oxidized by the current at the positive pole, and, what is more important, the secondary salt formed, an oxychloride of the metal, is driven or diffused by the action of the current into the tissue. In this case, unlike topical applications of washes, sprays or injections, the medication is not alone applied to diseased surface or tissue, but it is also driven into it, and may there act as a microbicid or a demurent. Early recognizing the value of this procedure, I at once, upon its publication in this country, established its use and greatly extended its scope by inventing new instruments, methods, and applications in my clinic at the New York Post-graduate School and Hospital.

Its gynecological applications will be referred to by the next speaker.

In trachoma, by a method established by the writer, no better treatment exists; with from one to two milliamperes of current a copper bulb electrode of positive polarity is slowly passed over the conjunctival surfaces; in a few days the sago-like granulations soften, and with successive treatments disappear together with the other distressing symptoms.

In chronic nasal and post-nasal catarrh I have reported cases of cure within from three to six weeks. To treat these cases the parts are first cocominized by a spray and then a bulb of copper, fitting upon a properly curved handle, is passed by the mouth to the post-nasal areas, until as much as possible of the tissue is saturated with the green oxychloride of copper dissolved by the action of the current off of the electrode; a current strength of from five to eight milliamperes is employed, the indifferent or negative electrode being placed upon the back of the patient's neck. Copper sounds and probes, properly protected, suffice to treat, in the same manner, the anterior nasal passages and recesses. A similar technique is applicable, with admirable results, in urethritis of a subacute or chronic type; possibly in an acute stage, but of this stage I have had no experience. The electrode, a proper-sized copper bulb, is withdrawn slowly, being always kept in motion, to avoid any chance of adhesion, and not to exceed two milliamperes of current is used. Should a slight adhesion occur, the polarity may be reversed a few seconds to loosen it. In all instances the copper instruments must be brightly polished with fine emery paper before use; after use they will be found to be deepened in color and corroded by the action of the current and to have lost weight.

I have also treated in this manner, and with a success unattainable by other methods, dermoid cysts, follicular tonsillitis, diphtheritic patches, vascular tumors, navi, lupus, epithelioma, pus sinuses, tubercular deposits, syphilis parasitica, and parasitic diseases, as well as many other diseases not here enumerated.

The simplicity of this method is readily realized, particularly in the use of copper and zinc needles; and with a galvanic battery, a theostat, and a milliamperemeter in hand, the practitioner may, if he pleases, simply fashion his own electrodes out of a piece of copper wire, by aid of a file and emery paper, or bend his wire in loops for probes or sounds, and be prepared to perform this far-reaching work of metallic electrolysis.

In a publication read before the American Electrotherapeutic Association this fall, and about to be published in the Journal of the National Association, of Chicago, I have fully detailed the technique and details of this procedure. Papers also have been published by my clinical assistants detailing my work and instruments, and by Dr. Clarence C. Rice, of New York, describing the same.

The instruments may be obtained of the Galvano-Faradic Company, 300 Fourth Avenue, New York City.
MORTON: ELECTRICITY IN MEDICINE.

The physiological properties of currents—namely, contraction of protoplasm, stimulation of nerve and muscle, fatigue of nerve and muscle ("anaesthesia" and paresis), electrotonus, and nutritional effects—have been dealt with, so far as time has permitted, in the section upon electro-physiology, and are here referred to only in a therapeutic sense.

The application of these properties of currents to practice requires of the physician no more than that usual knowledge of physiology which he would bring to bear in the intelligent use of other therapeutic measures. It requires also some technical knowledge of apparatus.

We will refer briefly to a few salient points coming under this branch of our subject.

Electrotonus.—This property of nerve (and of muscle) of having its excitability lowered at the positive and heightened at the negative pole is one of the fundamental data of galvanic-current treatment. It has become classical to treat the pain of a neuralgia by the positive pole. If the nerve is superficial, the advice is good; if it is deep, the electrotonic effect is not easily obtained.

Excitation and Fatigue of Nerve and Muscle, mainly Faradization.—No electrotherapeutic procedure is better established than is the use of the faradic current.

As now in use, it produces two effects—

a. Muscular contraction.

b. Sedation and numbness to pain (fine wire coil).

I should like to add, therapeutically, to these a third—namely,

c. A fatigue effect upon nerve and muscle.

Some three years ago, having occasion to treat a case of common orthopedic deformity where there existed a paralysis of one group of muscles and a spastic condition of the opposing group, it occurred to me, in place of cutting the tendons of the spastic group, to paralyze them for a time by the use of excessive faradization. The plan worked admirably, and the case, a most intractable one, got well. Arguing that, if faradization could exhaust nerve and muscle in this manner, in the numerous cases where it is commonly employed to treat paralysis it would easily exhaust the enfeebled muscle, I began to use milder currents and to use them intermittingly in order to afford the muscle time to rest and re-enforce itself. Confirming my results by others, I have since taught this method in my clinic.

Recently Dr. Xavier-Francois Debedat, of Bordeaux, has examined this question most exhaustively* by laboratory experiments upon healthy rabbits. The nutrition of the muscle is furnished by its blood supply; moderate contractions increase the intramuscular circulation, while severe contractions diminish it; the faradic current is a sort of electric gymnastics—its action resembles ordinary exercise; moderate exercise of muscles by a faradic current flowing in slow rhythm produces physiological hyper trophy or growth of the muscle; prolonged tetanization of the muscle by the faradic current flowing in rapid vibration produces fatigue and atrophy of the muscle.

The rhythm adapted to produce the best result in the growth of the muscle is one which affords about the same duration for the excitation and for the period of repose; this is about thirty faradic impulses per minute. I have devised a clock-work mechanism to secure this rhythm. It may be bought of the Kidder Manufacturing Co., of New York.

Consider for a moment how universal is the practice to treat paralyzed muscles, and those enfeebled by muscular atrophy, by simply subjecting them to the usual hummning or singing rate of vibration of the ordinary induction coil. The usual advice is to keep up their nutrition pending a period when their innervation may become more or less re-established. This practice is wrong if carried out by tetanization of the muscle. For such cases, the rate of the duration of the flow of the current should be about thirty waves per minute, thus allowing time to each excited contraction to subside and for the muscle to recuperate between contractions, as is the case in ordinary exercise. Faradize tetanization therefore, as now practiced, only further enfeebles and causes more atrophy of the paralyzed as well also as of the healthy muscle.

Nutritional Effects.—A strong continuous or galvanic current is, no doubt, a depressant to nutrition of tissue, local or general.

A mild interrupted galvanic current or a mild continuous galvanic current would appear to be stimulatory to nutrition.

A tetanizing faradic current, as has just been noted, retards nutrition, while a slowly rhythmic current (thirty per second) improves nutrition.

The highest order of nutritional effects are obtained by the use of franklinism, particularly when, as in the static induced current, an alternating or oscillating character of discharge is made use of.

The franklinic current alters the pulse rate, modifies the body temperature, produces a general vaso-motor dilata tion with a reaction of a feeling of warmth and well-being; and increases the organic combustions so that the amount of carbonic-acid gas and urea, together with other waste products, is largely augmented.

Its use is indicated particularly in cases of malnutrition. Classes of cases suited to this treatment are anaemia, chlorosis, neurasthenia, hypochondria, melancholia, gout, rheumatism, muscular rheumatism, neuralgia, neuritis, chronic synovitis, and chronic fibrous exudates about joints and tendons. Its local effects are often due to a deep molecular disturbance or perturbatory action set up within the tissue by the influence of the disruptive discharge or spark.

Time precludes any reference to electro-diagnosis.

In conclusion, I would say that I feel that I have scarcely touched upon the vast subject of electrotherapetics, and that I trust that what I have said may at least have the merit of falling within the scope of the title of our discussion—namely, Electricity in Medicine from a Modern Standpoint.

Conclusions.—1. I would suggest as a definition of electrotherapeutics, in a biological sense, that it is the transformation (by the law of conservation of energies) of electric energy into the energy peculiar to vital cells.

---

2. Electricity in medicine must be regarded not as an entity, like a drug, but as having a variety of "properties," such as electrolysis, cataphoresis, contraction of protoplasm, etc., each of which properties may be employed, singly or combined, to combat given morbid conditions or diseases.

3. Of the galvanic current it may be concluded—
   a. That strong currents depress nutrition of tissues and produce structural changes leading to physiological atrophy (twenty to a hundred milliamperes).
   b. That mild currents stimulate nutrition and produce physiological hypertrophy (one to eight milliamperes).
   c. That mild galvanic currents, pulsating or alternating, produce similar effects to mild continuous currents.
   d. That the negative pole is specifically indicated in that large class of cases termed chronic inflammation where newly formed fibrous tissue or exudate occurs.
   e. That upon the writer's theory—already accepted by several prominent physiologists—and observations, that catabolic or destructive events in tissue uniformly present the sign of negativity, that is to say, are at their origin electro-positive (resembling the zine of a voltaic cell), the negative pole is indicated to arrest the catabolism, the positive to augment it.
   f. That the positive pole is rarely indicated, and, if so at all, upon the basis of an electrotonic effect to produce sedation of neuralgia pain in superficial nerves.

4. Of the faradie current it may be concluded—
   a. That its main uses are to tetanize muscle and to cause sedation of pain.
   b. That the tetanizing current as now employed to treat paralyzed muscles is injurious, since it enfeebles the muscle and causes atrophic structural changes.
   c. That to strengthen or properly exercise a paralyzed muscle, a slow rhythm of the faradic current—about thirty waves to the second—should be adopted.
   d. That in some spastic conditions of muscles (due to paralysis of an opposing group) the strong tetanizing current may be used to advantage to overstimulate and thus to fatigue the muscle.

5. Of the franklinic current or statical electricity, it may be concluded that it is an adjunct of great efficiency in practice, since—
   a. It evokes the usual nerve and muscle reactions.
   b. It affords a most convenient means of stimulating the peripheral distribution of the nerves in the skin, producing counter-irritating, reflex, and other afferent impression effects.
   c. It has a local perturbatory action (spark).
   d. It produces profound alterations in the metabolism of the individual, increasing the natural waste products and diminishing the toxic or by-products. For this reason, it is specifically indicated in cases of malnutrition, whether local or general.

A Physician in Commercial Affairs.—We learn that Dr. Horace G. Norton has been elected president of the Trenton, N. J., Board of Trade, of which body he had before been vice-president.
will be silent and respectfully assent. If he should accept it, all the world, except the enemies of this country, will rejoice."

"That Rush was concerned in this cabal has often been denied," says Mr. Ford, "despite the fact that Washington subscribed to his pen the famous anonymous letter of the 12th of January, 1778, to Patrick Henry. But these denials cease to be of the slightest value in the face of this correspondence, which shows not merely that Rush was attempting to undermine his commander-in-chief at least three months before the anonymous letter was written, but even that he began his attacks before the convention of Saratoga, which, by its popularizing of Gates, gave such vitality to the conspiracy." Mr. Ford closes his article with this statement: "There exists today in Philadelphia a biography of Dr. Rush, in his own handwriting, in which frequent comparisons are drawn between himself and Washington, usually to the latter's disadvantage. Unfortunately, the publication or sight of it is prohibited, or still further light on this matter might be possible."

Mr. Ford is an experienced, cantions, and conscientious investigator of history, but we still venture to hope that the memory of Benjamin Rush, the great light of our profession in revolutionary times, will by some means be effectually purged of the stain put upon it by these letters. Unless it is, the proposed monument will be but a sorry affair, even if it is ever set up at all. Until his vindication is accomplished, we who have revered his memory can only grieve. We dare not question the authenticity of the letters to Adams, and of course nothing can exculpate them, but possibly the autobiography alluded to by Mr. Ford contains some recantation or explanation that, if published, would restore our confidence in Rush's sense of justice. There ought to be some very good reason for suppressing a famous man's own story of his life.

Perhaps, indeed, Mr. Ford's object in publishing the letters—we take it for granted that they are now given to the public for the first time—was to induce the custodians of Rush's autobiography to publish it, or at least to allow it to be examined. Without knowing what it contains that might be held to need concealment in the interest of somebody's reputation we can not judge of the propriety of its suppression hitherto, but so great a reason seems now to have been furnished for terminating that concealment, inasmuch as it is Rush's own conduct that is called in question, that it appears hardly defensible to go on holding the manuscript back. Many of our ancestors were intemperate in their language in revolutionary times, and it may be that to cover up some extravagance or undue heat of statement is the reason why Rush's autobiography has been kept away from public scrutiny. No such consideration as that ought to weigh now against its publication, provided there is anything in it that can mitigate the discredit which otherwise must attach to Rush's memory.

The late Dr. Samuel D. Gross, in his biography of Rush in the *Lives of Eminent American Physicians and Surgeons*, defended Rush against censure in the matter of the cabal, saying it had never been proved that he was included in it, and that, even if it had, it would have been of no consequence, for he would have been in the company of honorable and patriotic men, and, moreover, Washington was not then tried and known as he was afterward. Certainly such considerations would make open opposition tolerable, but they can not palliate machination, and that is what the letters to Adams signify. We hope yet to see some evidence that Rush subsequently realized and admitted, if only to himself in his unpublished and suppressed autobiography, that his course toward Washington had at least been founded on misinformation or misapprehension.

---

**MINOR PARAGRAPHS.**

**THE RETIREMENT OF DEPUTY SURGEON-GENERAL BILLINGS.**

We learn that Deputy Surgeon General John S. Billings, of the army, has requested that he be placed on the retired list; and that in October that distinguished officer will leave the Army Medical Museum, of which he is curator, and the Library of the Surgeon-General's Office, of which he is librarian, and these magnificent institutions, that have been made what they are largely by his ability and zeal, will know him no longer. Thus goes the last of the trio, Woodward, Otis, and Billings, that gave the army medical corps worldwide reputation.

Before the date he has selected for his retirement he hopes to complete his work on the final volume of the *Index-Catalogue*, a work that has made the medical profession of the world debtors to the United States Government, to the Army Medical Department, and, last but by no means least, to John Shaw Billings. In the *British Medical Journal* for April 20th, Mr. James Blake Bailey, the librarian of the Royal College of Surgeons of England, pays tribute to Dr. Billings by advising librarians and authors to adopt as standard abbreviations those used by Dr. Billings in the *Index-Catalogue of the Surgeon-General's Library*. The system, he says, "was well thought out and has thoroughly stood the test of use." A catalogue of the museum also has been completed under Dr. Billings' direction, and we hope it may soon be published.

In seeking official retirement Dr. Billings does not propose to give up work, as he has accepted the chair of hygiene in the University of Pennsylvania, and his energy will be likely to find congenial employment in the duties connected with it.

---

**THE ARCHIVES OF PEDIATRICS.**

In the May number of this excellent journal, the first issued under Dr. Crandall's editorship, we find a department of editorial articles. The leading article is on The Progress of the Infectious Diseases: it is an interesting one, mainly commenting on the health of the State of New York as shown by the mortality returns for the year 1894. The addition of editorials to the *Archives* seems to us a judicious move.

---

**A CHARGE OF PERJURY AGAINST A NAVAL SURGEON.**

It is reported that Dr. Edward Kershner, a high officer of the medical corps of the navy, is to be court-martialed on two charges. The first charge seems to amount only to that of a violation of regulations, perhaps a venial one; the second, however, is that of perjury in having sworn that he had not
done what is charged in the first. Dr. Kershner is an officer of long and honorable service, and we hope that he will be cleared of the charges; we should certainly not expect that the unfortunate coolness that has prevailed for years between the line and the staff of the navy would prejudice any of the members of the court. There must be some misunderstanding in the matter; we can not believe that Dr. Kershner has knowingly perjured himself.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending April 30, 1885:

Fowler, to No. 18 East Fifty-eighth Street, New York; Dr. Simon Marx, to No. 947 Madison Avenue, New York; Dr. A. Sohler, to No. 114 West Fifty-seventh Street, New York; Dr. Parker Sym, to No. 60 West Forty-seventh Street, New York.

**The Philadelphia County Medical Society.**—Owing to the fact that the meetings of the American Medical Association and of the Medical Society of the State of Pennsylvania fall this year upon May 8th and May 22d, regular meeting days of the Philadelphia County Medical Society, the latter society has substituted for these two meetings one meeting on May 15th, for which an extremely interesting programme is said to have been arranged.

**The Surrupitious Reporter** is going about in medical circles. This we infer from a communication sent to us by Dr. J. Mount Bleyer disclaiming his responsibility for certain alleged interviews with him on the subject of muelin at the German West Side Clinic. He says he spoke in the presence of a number of physicians, and did not know that a non-medical person was in his audience.

**Army Intelligence.**—**Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 21 to April 27, 1885:**

**Promotions:**

Baehr, Dallas, Lieutenant Colonel and Deputy Surgeon General, to be Assistant Surgeon General with the rank of Colonel. April 18, 1885.

Huntington, David L., Major and Surgeon, to be Deputy Surgeon General with the rank of Lieutenant Colonel. April 18, 1885.

Shannon, William C., Captain and Assistant Surgeon, to be Surgeon with the rank of Major. April 18, 1885.

**Naval Intelligence.**—**Official List of Changes in the Medical Corps of the United States Navy for the week ending April 27, 1885:**

Barlow, M. W., Assistant Surgeon. Ordered to examination for promotion on May 15th next.

Brathwaite, F. G., Assistant Surgeon. Ordered to the Naval Hospital, Norfolk, Va.

Dickson, S. H., Surgeon. Ordered as delegate to the American Medical Association, Baltimore, Md.

Page, J. E., Assistant Surgeon. Ordered to examination for promotion on May 15th next.

Walton, T. C., Medical Inspector. Ordered as delegate to the American Medical Association, Baltimore, Md.

**Society Meetings for the coming Week:**

**Monday, May 6th:** American Medical Publishers' Association (Baltimore); New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; New York Medico-surgical Society; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Boston, Mass., Medical Association (annual); Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chieno Medical Society.

**Tuesday, May 7th:** Louisiana State Medical Society (first day—New Orleans); American Medical Association (first day—Baltimore); New York Obstetrical Society (private); New York Neurological Society; Buffalo, N. Y., Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Cattaraugus (annual—Salamanca), Columbia (annual—Hudson), and Orange (annual), N. Y.; Hudson, N. J. (annual—Jersey City), and Mercer, N. J. (annual), County Medical Societies; Androscoggin, Me., County Medical Association (Lewiston); Connecticut River Valley Medical Association (Bellows Falls, Vt.); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

**Wednesday, May 8th:** Louisiana State Medical Society (second day); American Medical Association (second day); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Societies of the Counties of Albany and Allegany (annual), N. Y.; Pittsfield, Mass., Medical Association (private); Franklin (annual—Greenfield), Hampshie (annual—Northampton), and Worcester, Mass. (annual—Worcester), District Medical Societies.

**Thursday, May 9th:** Louisiana State Medical Society (third day); American Medical Association (third day); New York Academy of Medicine (Section in Pediatrics); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y. (annual); South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

**Friday, May 10th:** American Medical Association (fourth day); Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.; Cleveland, O., Medical Society.

**Saturday, May 11th:** Obstetrical Society of Boston (private).
Marriages

Married.

BAIRD—RENDELL.—In Brooklyn, on Wednesday, April 24th, Mr. William Wallace Baird, Jr., and Miss Violet Aurelia, daughter of Dr. and Mrs. John Rendell.

CARTER—KIEENAN.—In New York, on Wednesday, April 24th, Dr. De Laney Carter and Miss Margaret F. Kiernan.

OWENS—CAPERS.—In Columbus, S. C., on Tuesday, April 16th, Dr. Lawrence B. Owens and Miss Clara Stewart Capers.

Died.

BURTON.—In Troy, N. Y., on Sunday, April 28th, Dr. M. H. Burton.

SHIPEN.—In Baltimore, on Tuesday, April 23d, Dr. Edward Shippen, aged sixty-eight years.

Letters to the Editor.

Symphysiotomy in Texas in 1880.

William Penn, Texas, April 9, 1885.

To the Editor of the New York Medical Journal:

Sir: I have performed the operation of symphysiotomy (as I understand it) three times. The first operation was performed in Denison, Texas, in 1880. It was attended by such restrictive conditions that I can not even now give a complete account of it publicly; suffice it to say that it became necessary for me to save the child's life even at the expense of the mother, and I am satisfied that any physician who could be made acquainted with the facts that moved me to the action taken would bear me out when I say that I did right, even if I had been so unfortunate as to lose the woman.

After I moved to William Penn I was called to attend a woman who had been in labor all night. Upon examination, it was found that the point of one finger rested against the sacrum, and that that of the neighboring finger was just beneath the symphysis pubis. The soft parts were swollen and sensitive, having undergone a good deal of handling during the night. I could not pass even one blade of the forceps. I made an effort, as in the former case, to divide the symphysis with a tenotomy knife, but the knife was small, and under my efforts the shell handle was split. I then used a blunt curved knife, and finally succeeded in separating the bones, but they did not part as in the preceding case. I failed to extract the child, and resorted to craniotomy. I should now avoid resorting to the operation in a case of flattened, contracted sacro-pubic diameter.

In 1880 a gentleman sent me to see a negro that was living on his farm. The evidence in the case warrants the assertion that the woman had been in labor for five days and in contractions for thirty (not thirty-nine) hours. The last case had discouraged me, and I now thought of trying the Cesarean section, but the relatives were so opposed to it that I was about to give up doing anything. The landlord then said to me: "We must do something for the woman," and said that he would assist me in any possible way in whatever I thought best to do. It was night, and the only light was a "smuff-bottle lamp" (all the country brethren know just what I mean), which an old colored woman held while Mr. Dotson supported the patient's left lower limb. I separated the bones with a curved blunt knife very easily in comparison with my experience in the second case. The bones parted, I should think, to the extent of nearly two inches. The child was extracted and finally resuscitated.

An account of these operations was submitted to the editor of the Medical News more than a year ago, and Dr. R. P. Harris, of Philadelphia, became engaged in a correspondence that ensued and is not yet completed. Dr. Gould published an editorial based on the communication in the Medical News for January 26, 1885. Therupon Professor Charles Jewett, of Brooklyn, endeavored to throw discredit upon my story in a letter published in the New York Medical Journal for March 2d. Was such an attack honorable? Was it even permissible to publicly and viciously denounce and defame a fellow-being before that individual had by proper process been found unworthy of respect and confidence? Let any dispassionate, honest mind carefully consider Professor Jewett's letter, and I am sure the decision will be that he has for once appeared in print "inspired" with a determination to exterminate his victim. I admit that I have not enjoyed great opportunities of education, yet education is not the man. I have not had access to the associations and surroundings that tend to high professional attainments, but such attainments and associations are not the man. In the true man the trinity of truth stands as the basis of his career; after that should come education and improvement. Then the result is only a polished and improved man. But if in the man the principles of sincerity and unselfishness prevail, he may be educated and have every advantage, but those first principles will as a rule be the controlling elements in his life. I know, respect, and practice truth—more, I think, than Dr. Jewett has done in this instance. Even if I did bring forward the testimony of a layman, does Professor Jewett mean that such people are untruthful? If a farmer, any person of common sense, sees a thing with his own eyes—sees a knife inserted, feels the parts separated, sees the fingers depress the overlying tissue down between the separated bones, sees the forceps applied where before it had been impossible to do it, and sees the child extracted—is not that man competent to testify as to the procedure? That very woman makes an affidavit affirming what was done in the effort to save her child, also that I described the nature of the operation to her and insisted upon her obedience in every detail. Let those of my associates that hold me in disrespect speak for themselves. I am willing, because I know I have held out steadfastly for what I conceive to be right. If I have made mistakes, let him that is without sin cast the first stone.

The professor says loftily: "In a town of twenty-nine inhabitants," and adds "not a particle of medical evidence" (of course my evidence is here expunged), "no other physician was present," forgetful of the fact that doctors are not so accessible in a place of twenty-nine inhabitants as in a city of a million. Can Dr. Jewett be ignorant of the fact that the country fellows frequently have to undertake single-handed, with a simple pocket-case, what he himself would do with the aid of six assistants and a tray of sterilized instruments? Dr. Jewett says: "Dr. Williams says the pelvis was so contracted transversely that it was with some difficulty that two fingers could be passed," and then he adds contemptuously: "the condition in which delivery by symphysiotomy would have been clearly impossible." Yes, I say that the pelvis was so constricted that it was with some difficulty that two fingers could be inserted between the ischia—the very kind of distortion which holds out the greatest prospect of success, especially in young subjects. "Singularity enough, no laceration occurs," Dr. Jewett continues. This is the great argument in favor of subcutaneous symphysiotomy, as hemorrhage is greatly guarded against, and there is a very effective barrier to sepis. Then all the separation that is safe is obtained without division of the soft parts, and from what experience I have had in these three cases I question the advisability of severing the ligaments.
LETTERS TO THE EDITOR.

New York, April 27, 1885.

To the Editor of the New York Medical Journal:

Sir: Referring to the letter in the Journal of this date in relation to the effect of serum injections on the blood, I would state that your correspondent has misunderstood my position if he considers that I have confounded intravenous with hypodermic injections. Morphiine or any other drug acts more decidedly and rapidly if injected into a vessel rather than beneath the skin, but its ultimate effect is the same. So with serum.

The following thesis is submitted: In 1874 Malassez showed that there was lessened resistance of the red blood-corpuscles in disease: this fact is clinically familiar to all in the anaemia associated with many diseases. Héboul and Richet showed (Bullés eyl. et ol., tome ii. p. 389) that the blood of different animals of the same species was not equally toxic; they also showed (La Semaine méd., 1891, p. 21) that thirty grammes of dog's blood to each kilogramme of a rabbit might be introduced with safety into the peritoneal cavity of the latter animal, whereas if seven grammes were introduced into the veins the animal died, and it was imprudent to inject more than forty grammes of blood into the peritoneal cavity. The intraperitoneal injection of thirty grammes to the kilogramme was followed by profound disturbance in the rabbit's general nutrition, and the animal lost weight during many days. In the paper by Hayem referred to by your correspondent it is stated (Compt. rend. hebdl. des séances et méms. de la Soc. de biol., 1894, p. 586) that if blood serum is deprived of its coagulating properties and is injected into an animal it produces almost identical effects with those caused by ordinary serum; and these investigators hold that the pernicious effects following serum injections are due to intrinsic toxic properties of the serum. They made further investigations and learned that an alcoholic or ethereal extract of serum did not possess toxic properties, but the precipitate produced by the alcohol did.

From these investigations I deduce that the blood-corpuscles in diphtheria are, probably, as a consequence of the action of the toxine, easily subject to cytohemolisys; that the serum of the horse is not always the same, but contains a variable proportion of a toxic principle; that this toxic principle is slowly absorbed from subcutaneous injections, and notwithstanding its small dose produces cytohemolytic and toxic effects on the individual. That these facts are recognized abroad may be learned from Variot's report (La Sem. méd., 1895, p. 142), in which he refers to the hyperthermia produced by antitoxine serum, considers it due to a constituent of the serum, and advises that the antiphlogistic principle should be isolated from the serum so as to rid it of "an unstable vehicle that may become dangerous"; and to Sevestre's report (ibid.) that serum from a non-immunized horse injected into children suffering with non-diphtheritic sore throat caused febrile reaction and eruption. Clinically, symptoms have been produced in children by the hypodermic injection of antitoxine serum similar to those produced by Hayem (Du Song, p. 240 et seq.) by the injection of alicum serum in a lower animal; Lebreton and Magdelaine (La Sem. méd., 1895, p. 37) reported as a result of their experience at the Hôpital des enfants malades, that the antitoxine injections were not entirely harmless; that they might cause hyperthermia, lesions of the kidneys, and even in certain cases a deterioration of the general condition.

Other investigators could be cited in evidence of the fact that antitoxine serum is not, per se, harmless, and that the noxiousness is due not to the antitoxine, but to the serum from which it must be separated. And this latter subject is now a matter of research.

Samuel Treat Armstrong, M. D.
PROCEEDINGS OF SOCIETIES.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of January 2, 1895.

The President, Dr. C. C. Bamroes, in the Chair.

Rupture of the Uterus and Vagina during Labor.—Dr. J. Clifton Edgar presented a case of this kind, with the following history: Mrs. S., thirty years of age, pregnant with her sixth child, had gone into labor on November 24, 1894, at 4 p.m., a midwife being in charge. At 9 p.m. the membranes had ruptured, and the midwife had then recognized an abnormal presentation, and had turned the case over to a physician. The midwife, on being questioned, had denied that any medicine, such as ergot, had been administered, and stated that she had made only two vaginal examinations. The physician called to the case stated that he had made several unsuccessful attempts to deliver by version, and had then sent the patient to the hospital, where she had been admitted early on the morning of November 27th. The house physician had recognized a shoulder presentation in the left scapulo-anterior position, with a palpable of the right arm and the fandis. The patient had rapidly failed after her admission to the hospital, and had shown signs of collapse. As soon as possible podalic version had been performed, and no difficulty had been experienced in turning and extracting the placenta. An examination had revealed a utero-vaginal rupture of the genital tract, and the umbilical cord had been followed up into the peritoneal cavity. At this time no external hemorrhage of moment had taken place. Stimulants had been administered and preparations made for laparotomy, pending the arrival of Dr. Edgar, but the patient had died two hours and forty minutes after delivery and five minutes before his arrival. He had secured the placenta by passing a hand up through the vagina into the peritoneal cavity and removing it from among the intestines. The abdomen had then been opened and the genital tract removed. This constituted the specimen presented to the meeting.

The autopsy had shown a complete separation of the left lateral half of the utero-vaginal junction, with a rupture in the left wall of the lower uterine segment and in the upper part of the left vaginal wall. Death had been due to internal concealed hemorrhage, as several pints of fresh blood were found in the abdominal cavity. This hemorrhage had evidently come from the left uterine artery, which had been completely torn across.

The house physician stated that after the patient's admission to the hospital there had been no external evidences of hemorrhage other than the symptoms of collapse. The child weighed seven pounds. The right clavicle and humerus had been broken, and the tissues of the right shoulder had been bruised and cut as if by some sharp instrument.

The speaker said that this case illustrated the hopelessness of an expectant treatment of uterine rupture by gauze drainage where the injury had involved the uterine artery and hemorrhage had been going on into the peritoneal cavity, as well as the difficulty of determining the extent and character of the injury by vaginal examination alone.

Dr. W. Gill Wyile said he would of course favor laparotomy if it could be resorted to sufficiently early. Those who had been lost had died chiefly from our inability to reach the seat of trouble quickly enough. He had seen many cases where there had been partial rupture, and several where there had been tearing of the uterine artery. In evertting or treating the uterus soon after labor or abortion, it had not been uncommon to find the tissues exceedingly friable, and he thought that a similar condition of the tissues might be present in many cases of rupture of the uterus. He would be willing to attach a clamp or pass a deep silver wire suture in some cases so as to hold the gaping parts together, but ordinarily he would not favor primary suture.

Dr. Robert A. Murray said that the chief interest of the subject lay in the fact that this accident was very rare, and that consequently we were not usually prepared for it. He had seen only four cases of rupture of the uterus. In one case the medical attendant had first observed the patient suddenly become quiet, and then examination had shown a profuse flow of blood and a rupture into the broad ligament and peritoneal cavity. The child had been extracted immediately in this case, yet the mother had died. In another case, seen in consultation, the child had passed entirely into the peritoneal cavity. Labor had, of course, subsided. The hemorrhage had not been great, but the collapse had been very well marked. The attending physician said that he had heard the fetal heart after the rupture had occurred, so the speaker had drawn the child back through the rent. It had been found to be alive, but had spastically succumbed. Another case he had seen in the Charity Hospital, at the invitation of Dr. Coe, who had arrived about an hour and a half after the rent had occurred. The patient had been found in profound collapse. On examination, the speaker said he had found a narrow rim of cervix left and a rent into one broad ligament. The hemorrhage had been quite profuse and, although the patient's condition had been bad, it had been deemed wise to open the abdomen. On doing it he had found that the blood had passed into the broad ligament, and that the cellular tissue had become absolutely black and engorged from the infiltation of blood. The classical symptoms such as the sound of a tearing, its occurrence during a severe pain, and very profuse flowing had been absent, as in the case just presented. The important signs had been the sudden cessation of labor, and the appearance of collapse. In the case reported the laceration had been found to be in the segment between the cervix and upper portion of the uterus, but absolutely in the broad ligament. In such a case as this, he thought, treatment by tamponade would have been the best. It had been proposed that these patients should always be laparotomized, but in his opinion it was exceedingly bad practice to make this a routine measure. The collapse of the patient, the great prostration, the almost inevitable delay in procuring instruments, and the severe hemorrhage, were all contraindications to laparotomy. The operation usually only added to the shock, and the patients were almost always lost. Statistics from the Vienna Maternity Hospital had shown this very plainly. They had saved about fifty per cent. of the patients treated by the expectant plan. If there was arterial bleeding it could not be controlled by the tamponade, hence it had seemed to him proper in such an emergency to grasp the edges of the rent by clamp forceps. To be sure, this was largely working in the dark, but the pulling down of the uterine to assist us in this manipulation was in itself an excellent means of controlling the hemorrhage. The introduction of a silver suture, as suggested by Dr. Wyile, was also a valuable means at our command. He did not believe in a haphazard introduction of gauze, for, as the uterus was in a friable condition, once was very apt to tear the uterus still further, to say nothing of the fact that unless the packing was carefully and systematically done one could hardly expect it to be an efficient means of controlling the uterine hemorrhage.

In conclusion, he would advise very strongly against performing a laparotomy on most of these patients, on account of
the condition of collapse usually present. He said this, notwithstanding the fact that most of the text-books laid this down as the usual and proper method of treatment.

Dr. Wylie said that before we condemned laparotomy this method of treatment should be given a fair trial. Up to four or five years ago the practice had been to stimulate the patients before performing laparotomy, and, as was well known, these patients had usually died. He had performed laparotomy on at least two patients, already in marked collapse, and had succeeded in saving both. We should therefore exercise the greatest care and judgment in deciding under what circumstances laparotomy held out any hope of saving these patients.

Dr. Murray said that if there was an extra-uterine pregnancy and the patient bleeding, there was, of course, no other way of stopping the hemorrhage than by performing laparotomy, but in the case of rupture of the uterus there was an opportunity of gaining access to the bleeding point and controlling it without resort to laparotomy. The physicians in Vienna had obtained very superior results from the tampon as compared with laparotomy.

Dr. Engan said that there had been a suspicion that ergot had been given by the midwife in the case reported, but she had positively denied that she had done so. In Vienna the statistics, he thought, showed that the mortality was about the same from laparotomy and from the expectant treatment with gauge. Most of the thirteen patients that had been lost had been treated by the expectant plan, and a large portion of these had died of sepsisemia. Many of them before entering the hospital had been treated by midwives, and had been made septice before admission. Experience had led them in Vienna to conclude that in cases which had not been made septic the patient had a better chance for her life if she was drained with gauge. The mortality by any method was about seventy-five per cent.

Fracture of the Neck of the Radius.—Dr. Parker Sym presented a boy of five years who had recently sustained a fracture of this kind. The mother stated that the injury had been caused by a forcible twisting of the forearm. The symptoms had been a slight apparent swelling at the center and lower part of the elbow, the production of crepitus on rotating the forearm, and a false point of motion, which had been distinctly felt just below the head of the radius. The fracture had been just above the tuberosity, and the patient could flex the forearm, as the biceps attachment had not been disturbed. The speaker regarded the case as one of separation of the epiphysis.

A Large Enterolith.—Dr. Wylie presented a large calculus which he had removed about a week previously from a woman. She had given a history of having had some years previously a series of attacks of what had been supposed to be hepatic colic. The illness in question had begun with pains about the stomach and a tendency to vomit. Her physician had made attempts for three days to move the bowels, and then failed vomiting had set in. The speaker said that he had first seen the patient at this time and had advised feeding her entirely by the rectum. The next morning he had found a slight fullness just below the liver. He had operated by an incision such as would have been made in an operation for gall-stone, and he had found the stomach adherent to the edge of the gall-bladder. The gall-bladder had appeared to be normal, and no obstruction had been found in the gall ducts. After having enlarged the original incision he had felt this calculus in the small intestine, and he had then opened the intestine and removed it. Since the operation the patient had done well. The stone, by causing an obstruction at the ileo-cecal valve, had given rise to the symptoms. The stone was cylindrical in shape, and was about two inches long and an inch wide. The composition of the stone had not yet been determined.

A Metallic Catheter broken off in the Male Bladder and Urethra.—Dr. J. F. EKDMANN reported such a case. The patient, S. N., sixty-seven years of age, had had an enlarged prostate for seven or eight years. On November 11, 1893, his family physician had tried to introduce a silver catheter, and, while making “the curve,” without exerting any unusual force, the catheter broke. The speaker had seen the patient shortly afterward, and had been shown the two upper joints of an ordinary pocket-case catheter, the first joint of which had been broken off within the urethra. The genitals had been bloody and painful, and the bladder could be readily outlined on the abdominal wall. On palpating the perineum, a pipestem-like body could be felt for about an inch and a half from the arch of the pubes. With the finger in the rectum, nothing but the enlarged prostate could be felt. On making firm pressure with the left index finger under and against the arch of the pubes, and with the right hand pushing the penis down upon the mass, as one pushed a glove on the finger, it had been possible to grasp the tip of the foreign body through the penis. Then, by making the same movements as in withdrawing a steel sound, he had finally been enabled to feel the tip of the catheter per rectum. By a continuance of the same movements, aided by the pushing force of the finger in the rectum, the upper extremity of the piece of catheter had been brought out of the penis. A considerable quantity of blood clot had been passed after this. It had then been found that the upper or screw end of the joint of the catheter had but two turns and a half remaining, and had been fortunately broken off comparatively smooth, thus accounting for the success of the manipulations undertaken for its removal.

Actinomycosis.—Dr. ALEXANDER LAMBERT presented two specimens showing pure cultures of actinomycosis. They had been obtained by a very simple method—viz., the small nodules of actinomycosis had been thoroughly washed in several dishes of sterilized water, and after this washing had been dropped upon the broth.

(Tо be continued.)

Book Notices.

In this work of a thousand pages, by eminent American teachers, as the title announces, we have the ripe thought of mature minds in a form which is highly creditable to the American profession.

There is no specialty in medical science in which aggressiveness and progressiveness are more marked than in gynecology, and there is none in which the literature more fully keeps pace with the thought. Monographs and “systems” follow each other in quick succession. It is scarcely a year since a work similar to the one which is under discussion was launched upon the market, while three others by single authors have appeared within almost the same period.

The criticism has been advanced that works like this one, varierum works, are deficient in the conciseness and effective-
ness which result from the labors of a single master-mind. It is said that, however meritorious a series of essays or monographs may be, there must inevitably be no little overlapping or repetition in the consideration of closely allied subjects; but we wish to say distinctly that we consider this an advantage rather than a drawback. For example, in this book certain phases of menstruation are considered in the sections on Methods of Gynecological Examination and Outlines of Gynecological Therapeutics, while the entire subject of menstruation is fully and admirably treated of in the section on Functional Diseases, and thus the reader has the advantage of having the lights and shadows of the subject depicted from different standpoints.

Very touching is the tribute which is paid to the memory of the deceased senior editor of the work. The brightness of that light which was too soon extinguished will be concealed by those who are at all familiar with recent American medical literature, which Keating did so much to illuminate and adorn.

The same is eminently true of the brilliant and versatile Goodell, whose introductory essay causes a thrill of pain, for it reminds us that the skillful hand, skillful alike with the pen and with the knife, is forever palsied, that the warm heart has ceased to throb. The courteous Christian gentleman whom none knew but to love is now with us in memory. The words of hope and obligation in his essay become, alas, mortuorum solutaneus. There have been many eminent teachers and practitioners of obstetrics and gynecology in Philadelphia, but none more eminent or worthy than he. Warm discussions have marked the progress of these sciences in that city, but, however heated they may have been, the urbanity and courtesy of Goodell were unflagging. Aearth! vale!

An interesting feature in this work, compared with others of a similar character, is its greater comprehensiveness. Not only are those themes discussed which have hitherto been recognized as purely gynecological, but also, with greater breadth of view, those which are collateral and related, including diseases of the breast, the rectum, and the anus. It is to be hoped that this may serve as a useful example to future authors and editors. It has always appeared singular to us that these subjects have generally been ignored in gynecological text-books. The mammary glands are certainly an essential part of the genital apparatus, and certain morbid conditions of the rectum and anus are inseparable from disease of the pelvic organs in women.

So broad, indeed, has the field of gynecological surgery become that it could scarcely be considered inappropriate if the lesions and neoplasms of all the abdominal viscera which may complicate or simulate disease of the pelvic organs were discussed in a work of this character. Abdominal surgery owes very much to gynecologists for its present high development. It is logical and inevitable that one who works in this field to any extent should familiarize himself with it in all its phases and varieties.

The illustrative portion of a work of this character is a most important one; the text alone must always be insufficient. We are happy to commend that feature of the work under discussion; but we must add that we object to the introduction of portraits; it savor s too much of the prevailing mania for such representation in the daily papers. For the general character of the work we, in common with the large circle in which its influence will be felt, offer hearty and unhesitating praise. Most of the names with which its pages are adorned are too well known for anybody to question the authority with which they speak. On some of their subjects the last word has been spoken, displacements probably, pelvic inflammation perhaps; on others, such as the vaginal route for pelvic and abdominal operations, we may have to retrace our steps and re-write our opinions.

---

The author has aimed, he tells us in the preface, to make a practical book for general practitioners and students, and we think he has succeeded most notably. The whole plan of the work and its execution show that he has an accurate idea of what it is that medical men in general wish to know about a subject. Hence he has avoided theoretical discussions, historical accounts, and the niceties of operative technique. An excellent feature of the work is that the author gives modes of treatment as they are actually practiced in America, so that he justly hopes it will be found by American physicians and students more useful than similar books written by foreign authors.

The text is arranged in two divisions, general and special. The first deals with the generalities of anatomy, physiology, and etiology, with the examination of patients, and with treatment in general; the second, with the diseases, malformation, and injuries of particular parts. It is not our purpose to subject the various chapters to critical consideration seriatim; we shall only call attention to a few features that seem specially noteworthy. The book is quite comprehensive, and we think the author is to be commended for having given it this character; its scope includes venereal affections of the genitals, but diseases of the breast are not considered, and those of the urinary tract are noticed only briefly, except in connection with fistula. Special chapters are devoted to hemorrhage and leukorrhea. For this the author says he expects to be criticized, but we think he was wise.

The anatomical descriptions are brief, but full enough for the purpose; they are clearly written, and they bring out the embryology in its proper significance. The descriptions of particular parts are followed by short statements as to their functions. A few of these paragraphs on function seem a little fanciful; for example, speaking of the pubic hairs, the author says: "During copulation these hairs come in contact with the corresponding growth of the other sex, and by the irritation thus caused in the nerves at their root give a pleasurable sensa-

Dr. Garrigues's remarks on massage, which the limits of the book have not allowed him to describe save in the most general terms, seem to us very judicious. He says: "The procedures being rather painful, there is no danger of causing sexual excitation. The manipulations are quite complicated, have to be adapted to the special abnormal conditions obtaining, and can hardly be learned except by seeing them carried out by an expert. Unfortunately, this treatment requires so long sitting that a gynecologist or general practitioner will hardly find time to use it himself, and, on the other hand, such fine diagnosis is necessary that nobody who has not a large experience in abdominal examinations can be entrusted with it."

The therapeutical virtues of gold having of late excited unusual interest, we note that Dr. Garrigues gives it as his impression that chloride of gold and sodium has a decided effect as a resolvent, especially in chronic oophoritis. He thinks that cotton root is superior to all other homoeostatics in chronic cases, whatever the cause of the hemorrhage may be. He prefers a decoction made fresh every morning by boiling three heaping teaspoonfuls of rasped cotton-root bark in a pint of water for a quarter of an hour. By the boiling it is evaporated to half a pint; it is then to be strained and taken in three doses during
the day. This deception, he says, not only checks hemorrhage, but seems to have a tonic influence on the uterus and on the general health.

We are glad to find the following in the section on pelvic cellulitis: "Some modern gynecologists would have us believe that inflammation is rare in this tissue [the connective tissue within the pelvis], and that when it does occur it rarely runs into suppuration. It is an unfortunate but common quality of the human mind to be engrossed by one idea to the exclusion of others. When a new discovery is made we are apt to be dazzled by it to such a degree that we overlook other equally well-established facts. There was a time when every pelvic inflammation was looked upon as cellulitis; then there came a reaction and it was all peritonitis; and of late many exclusively lay stress on salpingitis. As a matter of fact, connective tissue in the pelvis, just as anywhere else in the body, is prone to become inflamed; but as a rule we have only clinical evidence of its existence. Since the patients usually recover, we have only a few anaptyles to fortify our argument with. Yet we have some performed on women in which the inflammation was strictly confined to the connective tissue, without impaling peritoneum, tube, or ovary, and there is the still more convincing case of a man who fell asleep on a wet bridge, and in whose pelvic connective tissue a large abscess formed, while the peritoneum was entirely free. In this case certainly no periperal influence could be invoked, nor could the cellulitis be attributed to uterine, tubes, or ovaries. Some gynecologists express themselves as if the disease did not concern them when it is connected with childbirth and abortion; but, even if they do not practice obstetrics, they are very likely to be called in when an operation has to be performed, and science is one, independently of the limits within which the physician may find it convenient to confine his work. But, even independently of periperal influences, cellulitis exists, and if we do not see it in laparotomies as often as we find peritonitis it is for the simple reason that few laparotomies are performed when the inflammation is limited to the pelvic connective tissue."

In general Dr. Garrigue’s style of writing is simple and clear—wonderfully so when we reflect that proficiency in the English language was probably not seriously attempted by him until comparatively late in life. Except in very rare instances, his meaning is perfectly plain. One of these exceptional cases occurs in the section on tricholopharygia, where we find (on page 387) the following sentence, which seems to us somewhat obscure: "The result of the cutting is that we have four denuded surfaces, which two and two meet together in the depth of the angle, and between the denuded surfaces a trumpet-shaped undamaged piece of mucous membrane." We presume the accidental omission of a few words accounts for the ambiguity of the sentence "If the urine is only saturated," etc. (page 192, ninth line from the foot). There seems to have been a slip also in the expression "6 parts of chloride of sodium in hot water" (page 171); the number of parts of water is not indicated. We have noticed only one harsh violation of good English, and that is on page 507, in the phrase "the sick tubes," meaning of course the diseased tubes. On page 592 there is a foot-note beginning: "This subject was first treated by Dr. Mary Dixon Jones, and has been corroborated," etc. Now, evidently Dr. Garrigue does not mean to say that the subject has been corroborated.

In his choice of words the author is generally most judicious. He does not like hybrids, and we therefore wonder that he uses the word vaginitis, merely remarking that the German substitues copitis for it and that erythris is sometimes used by English writers; eurytris is often employed, and we are sure every reader would have understood it. We are glad to find that the author objects forcibly to the word coelitomy; to our thinking, his objection is perfectly sound. In at least one instance he has fallen into the indefensible practice of hyphenating two men’s names together to form a possessive—thus (page 472) "Schroeder-Hoffmeier's method." Purely typographical errors are not common in the book; we have noticed the following: "Tympanitis" for tympanites, "Englemann" for Engelmann, "cathartic" for caterhart, "Ferguson’s" for Ferguson’s (but not in all instances), "laparotomy" for laparotomies, and "Bennay’s" for Bersay’s.

The typography of the book is good, and the press-work has been well done. The illustrations are for the most part apt and well enough executed to serve the purpose; one of them, Fig. 105, shows Sims’ posture very well. Color is used in three of them, not to very great advantage, we think.

Nearly everything that we have here said of the work has been commendatory, but we wish to add specifically that we think it one of the few really good books on gynecology for the general practitioner.

The uric-acid condition has long been a study of absorbing interest, and so much would seem to depend upon an understanding and a solution of its mysteries that all that concerns it must be of interest to the medical profession. To an elucidation of its intricacies the work of such men as Garrod, Haig, and Roberts has contributed much, and, though much remains to be found out and though, owing to the diffculties attending the study, it is not remarkable that many mistakes have been made and many false theories advanced, yet certain distinct and proved gains have been made. Anything, then, which can add to our knowledge of the subject is most important, and Dr. Levison’s work does add to it in no small degree. His book is a collection of all the important work that has been done upon the subject and an argumentative and logical consideration of the information so advanced. To this is added much original work, with the result of giving us a presentation of the subject in its most recent and advanced aspect. Some of his conclusions are of so much interest that quotation will not be necessary.

Of the physiological significance of uric acid he says:

1. Uric acid is formed in the body by the disintegration of the albuminous substances of its tissues, especially of the nuclein or nuclei.

2. The excretion of uric acid becomes increased or diminished by all factors (diseases, medicines, poisons, etc.) which give rise to a more rapid or slower disintegration of the cellular elements of the body, and especially of the leukocytes.

3. The taking of food, especially flesh food, causes a temporary leukoeytosis (digestive), this leukoeytosis probably arising from the nuclein of the food.

4. The amount of uric acid excreted in twenty-four hours is not influenced to a great extent by food. There is, however, this distinction noticeable: the easily digestible animal albumins set up digestive leukoeytosis and formation of uric acid much quicker than the vegetable albumins, which are difficult to digest.

Of lithiasis he concludes that, "When the chemical composition of the urine is such that uric acid becomes deposited in the kidney, the crystals are first of all laid down in the tubules of the cortex, tubes contorti, etc. As long as they are not numerous they may be washed out by the flow of urine without giving rise to any particular inconvenience. Under special
The first part of the book treats of cool-liver oil, and is charmingly written. It is a historical, descriptive, and statistical consideration of the oil and everything which concerns it, from the time the fisherman starts in pursuit of the end to the time when the bottled oil is put upon the market. It is true that the whole treatise is in the interest and to the glory of the Moller process, and therefore, strictly speaking, proprietary, and yet there is so little of proprietary bragging and so much of modesty and honesty in it that the work rises above its class. We know of no work on cool-liver oil more complete, interesting, and satisfactory than this, and the analytical parts of the work and the discussion of the various "preparations" and "substitutes" the market has from time to time contained are of special value to the physician.

The second part of the book is a diagrammatic work on organic chemistry. The object of the author is to simplify the subject and make it interesting by a new system of graphic formulae. His system is good, the formulae are interesting, and the text generally is excellent, but we scarcely think the subject so important to the practitioner as the author would have us believe, and we doubt whether the physician will find time and inclination to learn chemistry from a picture book, even if it is a good one.

To say that the Medical Annual is one of the most useful books with which we are acquainted and one which most successfully attains the object of its editors is no slight praise, and yet it is certainly justified. The work is so well known, however, that it seems unnecessary to say more than that this volume is in every way worthy of its predecessors. Of course the most important novelty is that of the diphtheria antitoxine, and, though it is going too far to say that anything absolutely essential pertaining to it has been omitted, yet the chapter is brief to the degree of failing to satisfy, and might well have been made more generously inclusive.

We can not refrain from mentioning what we think a mistake in the make-up of this book and one we have criticized before, and that is the enormous amount of space given to advertisements within its covers. The text of the book occupies something over six hundred pages and the advertisements about a hundred and fifty. And not only is the text preceded by an advance guard of thirty pages of these advertisements and followed by a rear guard of over a hundred, but even the title pages, the pages of contributors, the pages of contents, and the preface are interleaved and backed by matter of the same class. For example, page xxxii informs us that this is The Medical Annual and Practitioner's Index, and page xxxii that Nestle's food is "an entire diet for infants, children, and invalids." Page xxxiii repeats the name of the book and gives us information of its editors, contributors, and publishers, while page xxxiv tells us that "Johannis is "‘the king of natural table waters." All this is bad, for the text is too good for its company, and while advertisements no doubt "pay," it seems a pity that the procurer of this book should be obliged to buy so many of them. For these reasons we much prefer the American edition, which is sold under the name of The International Medical Annual.

**BOOKS, ETC., RECEIVED.**

**System of Surgery.** Edited by Frederic S. Dennis, M.D., Professor of the Principles and Practice of Surgery, Bellevue Hospital Medical College, etc., and assisted by John S. Billings,
MISCELLANY.

Amputation of the Entire Upper Extremity (including the Clavicle and Scapula) for Sarcoma following Fracture of the Clavicle. Extensive Thoracoplasty by Schelder's Method. By W. W. Keen, M. D. (Read before the Philadelphia Academy of Surgery, February 4, 1895.)

Amputation of the Female Breast. By W. W. Keen, M. D. [Reprinted from the Clevelan Medical Gazette.]

The Surgical Treatment of Inguinal Hernia. By Henry O. Marey, M. D. [Reprinted from the Transactions of the New York State Medical Association.]

A Valuable Discovery. The Cure of Impotency. By Hugo Engel, M. D. [Reprinted from the Medical Summary.]

Modern Surgery of the Pelvic Floor in Women. By George H. Kirwan, M. D. [Reprinted from the American Gynecological and Obstetrical Journal.]

Vaginal Cœliotomy. By Hiram N. Vineberg, M. D. [Reprinted from the Medical Record.]

Miscellany.

The Dietetic Treatment of Chronic Bright's Disease. The April number of the Quarterly Medical Journal for Yorkshire and the Adjacent Counties contains an article on this subject by Dr. W. Hale White, of Guy's Hospital. There are few, says the author, who would be inclined to dispute the statement that the dietetic treatment of chronic Bright's disease is a very important subject, and its importance has been enhanced of late years by the statement so often made that the ideal food for the patients is milk. According to Lépine, milk is the ideal diet, for it replaces the albumin that the patient loses, all its nitrogen is absorbed and used, it does not irritate the kidneys, and it is diuretic and aids the elimination of the toxins. For the past few years the author has carefully examined the title of milk to be considered a perfect food in chronic Bright's disease.

Milk is said to diminish the amount of albumin, but, he says, this is not by any means always true, and he has seen many cases illustrating the falsity of the statement. It must be remembered that if milk did decrease the albuminuria, there is no proof that this is of any benefit to the patient. Patients who are very ill with chronic interstitial nephritis may lose only a few grains of albumin a day. This can not, of itself, says Dr. White, be of such importance, as the absorption from the intestine of a very little more albuminous material would, if not lost in some excretion, quickly make up the deficiency. The majority of persons who pass albumin have not Bright's disease at all, but are suffering from heart disease, pyuria, specific fevers, etc. All these and other considerations indicate that even in a case of Bright's disease in which the loss of albumin is considerable this of itself is really not quite so important as is usually thought. If it was, restricting the diet to food containing less albumin than ordinary ought to be harmful to the patient, for not only would he be losing more albumin than when in health, but he would be taking in less. Then, too, it must be borne in mind that even in cases of Bright's disease where the change from a milk diet to meat increases the albuminuria, unless this increase is considerable, it is not so great as the increased absorption of albumin is, which is due to the fact that the meat diet contains more albumin than milk. The conclusion is, says the author, that the amount of albuminuria in chronic Bright's disease is of itself unimportant; that it is often more under a milk diet than under others; that even if it is more upon a meat than upon a milk diet, the increase is, nevertheless, usually more than compensated for by the increased absorption of albumin.

It is frequently urged, says Dr. White, that milk is easily digested, but his own experience is that often this is directly contrary to fact. He has noticed that patients suffering from chronic Bright's disease who are fed solely upon milk suffer from indulgence, that the milk by its mere bulk tends to dilate the stomach, and that it also causes constipation. With regard to its diuretic qualities, the author has observed this fact about it, but he has also frequently met with cases in which it was not diuretic. The theory that milk is less irritating to the kidneys than an ordinary diet, and that it contains fewer toxins, comes entirely, he says, from the study and not from the bedside.

Dr. White has convinced himself that none of the reasons urged in favor of a milk diet are valid, and he goes on to consider the effect of different diets upon the excretion of urea and upon albuminuria; the effect on the general health of the patient; the effect on the circulation; and any exceptional cases for which milk is suitable. The author relates the histories of several cases with regard to the excretion of urea and albuminuria, and the conclusions to be drawn from them, he thinks, are that the effect of diet upon the excretion of urea is most uncertain, for it does not follow that more protein in the food means more urea excreted; in fact, the reverse is often true. Moreover, a milk diet is much more likely to induce albuminuria than an ordinary diet, and that, consequently, those who are constantly shewing slight uraemic symptoms should take the usual food of healthy persons.

As to the effect of diet on the general health, Dr. White says that he has watched his patients closely and has noticed that they always felt better on an ordinary diet than on one of milk; even if they are on a farinaceus diet, their health improves if meat is added to it. In the Observations sur le régime lacté absolument dans l'albuminurie for 1893, says the author, Vergely protests most strongly against the use of milk in chronic Bright's disease, for it leads, he says, to weakness and causes digestive troubles that prevent all further treatment, and it leads also to a diminution of weight. In this opinion Dr. White fully agrees.

The next thing to consider, he says, is the effect of various diets upon the circulation, and from what has been said it is clear that a full ordinary diet containing meat should be expected to act as a cardiac stimulant, which is exactly what it does. Nothing is more striking, says Dr. White, than the alteration which takes place when a patient who has a feeble circulation from cardiac failure, bronchitis, or some other cause, and has been on a milk diet for some time, is put upon an ordinary diet. The pulse becomes fuller, the circulation improves, and the esculenta may even diminish. There can be no doubt.
MISCELLANY.

whatever, he thinks, that in cases of chronic Bright's disease with a feeble circulation ordinary diet containing meat is an excellent thing, and the good that is done is due largely to the cardiac stimulant action of the extractives in the meat. For the same reason this is just the class of cases in which a little alcohol is beneficial, for it not only aids the circulation but improves the digestion.

With regard to a consideration of the cases for which a full diet is undesirable, says Dr. White, a diet composed largely of meat must be given with caution to patients in whom the pulse tension is high and the hypertrophied heart is acting powerfully, for in such cases the chief danger lies not in uraemia, but in haemorrhage, especially cerebral. The extractives in the meat, acting as powerful cardiac stimulants, will increase the force of the heart, raise the blood pressure, and greatly add to the liability to cerebral haemorrhage. But we ought not, he says, unless the pulse tension is very high, to fly at once to the other extreme and give nothing but milk, for it must be remembered that the high-tension pulse is in itself probably evidence of a uraemic condition, which, it has been seen, is rather accelerated by milk. For the most of such patients it will suffice to order small meals, one or two more in the day than usual: they should be advised also to take a little fish and fowl rather than beef and mutton—a little fish or bacon with a little toast and tea for breakfast, a sandwich or two at eleven o'clock, a few oysters for luncheon with bread and butter, chicken with vegetables, bread, and a sweet for dinner, and a glass of milk the last thing at night, peptonized if the digestion requires it. Alcohol should be avoided altogether if the pulse tension is high, for its action as a cardiac stimulant tends to increase it.

An ordinary diet, says Dr. White, should be avoided when the patient is the subject of acute Bright's disease. We know, he says, that one variety of it is part of a specific fever, and the other variety is in its sudden onset, its pyrexia, the close resemblance of the pathological changes in the kidney to those in the lung in pneumonia, and in many other points, very like a specific fever, and, just as we have learned that pneumonia is a specific fever, so some day perhaps we shall discover that acute Bright's disease is a specific fever, and we know that during febrile processes the patients do best on a liquid diet. For this reason the author usually prescribes milk or a farinaceous diet for patients who are suffering with acute Bright's disease.

Rupture of the Uterus at the Onset of Labor.—In the Lancet for April 13th Mr. William Harris Best, of London, relates the following case, on account of its rare occurrence: The patient, who was thirty-two years old and the mother of seven children, and had been accustomed to hard work, had been attended in her previous confinement by the author about eighteen months before the present one. She never had had any miscarriage or any symptoms of syphilis. The author was sent for, and on his arrival was told by the nurse that a haemorrhage had occurred from the vagina. Only one pain had occurred, and had been followed by a gush which she thought was the liquor amnii following the sudden rupture of the membranes. The haemorrhage ceased when the nurse changed her from the right to the left side; continuous pain was from this time felt on the left side of the abdomen. After waiting about three quarters of an hour, as labor pains had not come on, Mr. Best was sent for. On his arrival he found the patient had rather an anxious look on her face. The left-sided pain, though not severe, became so if the abdomen was handled or if she was moved or attempted to move herself. She appeared very nervous and upset, so that it was difficult to tell definitely whether the pain was very acute or the tenderness very great, as she cried out as soon as the vulva was touched in making a vaginal examination. There was practically no collapse, and the depression was only such as might have been produced by a slight haemorrhage. Her pulse was fairly good, eighty beats to the minute. The patient appeared to be very much disturbed at the pro-pect of being touched or examined. The pain was confined to the left side and was not severe, the patient talking in an ordinary way and not complaining unless she attempted to move. On vaginal examination the author at first failed to reach the presenting part or, indeed, the os; on inserting the whole hand into the vagina, however, he could get his middle finger inside the os only about a third of an inch, but felt nothing definite. Though the patient said she had felt movements of the child shortly before labor, he could not hear the fetal heart sounds. Abdominal palpation yielded no definite result, as the patient could not bear it being done properly. Nothing definite was thus made out by either examination. The patient now begged to be left alone for a time, and, as her pulse remained fairly good and there was but little pain, her request was granted. Neither labor pains nor haemorrhage occurred for the next hour; her pulse remained about the same, and she became rather more comfortable. At this stage the case looked like either a placenta previa or slight accidental haemorrhage, the pulse keeping good, and the patient not complaining of feeling faint or exhausted appeared to place concealed hemmorhage or ruptured uterus out of the question. As at this time the patient's condition appeared to be improving rather than going back, the author decided not to use any means for bringing on labor, at least for a time, other than plugging the vagina and orifice of the womb, which latter would answer the double purpose of preventing further external haemorrhage and keep up a slight reflex stimulation on the womb. This was carefully done with iodiform wool pellets. A few hours after this the patient did not appear to have altered much. She took nourishment and kept it down; her pulse was, however, quicker, her face looked more anxious, and a feeling of sickness was complained of. Her temperature in the mouth was 101° F. Mr. Best now decided to endeavor to accelerate labor by resorting to more active measures. No haemorrhage followed the removal of the plugging. On making a vaginal examination a hard, indistinctly fluctuating mass was found in front of the anterior vaginal wall and remained after the bladder was emptied. A Barnes's bag was with difficulty passed through the os, the difficulty not arising from the rigidity of the os or any malposition of it, but from its great height. Ergot was given by the mouth freely. No real labor pains followed, though about an hour afterward the bag was found in the vagina and the os readily admitted two fingers. Still no presenting part could be definitely made out. The next size Barnes's bag was easily passed, and after a time, on its removal, three fingers could easily be passed through the os and a shoulder was found presenting. Without much difficulty, by means of the bipolar method of version, a foot was brought down into the lowest and posterior part of the uterus. The child was found to be dead, skin peeling off the foot. The passive condition of the uterus during removal of the child was noticeable. No blood or liquor amnii up to this time had escaped. A rupture in the anterior uterine wall could now be detected. The placenta, which was found to be quite free in the uterus, was easily brought away, the uterus remaining flaccid. Epidural injections of ether and ergotamine were now given, as the patient complained of feeling faint. She quickly revived. The uterus could not be made to contract, though not even an ordinary amount of external haemorrhage occurred. An iodiform and eucalyptus suppository was left in the upper part of the vagina with its apex passing through the external os, and repeated every six hours. Sickness gradually increased, and the patient
died thirty-six hours after the birth of the child with symptoms of peritonitis and exsanguination. No post-mortem examination could be obtained.

The points worthy of particular notice in this case, says the author, appear to be the very early stage at which rupture occurred; the absence of any other exciting cause than the faulty position of the child (no marked anteversion of the uterus being made out); and the comparative mildness of the first symptoms occurring after so grave an accident.

Chlorobrom as a Hypnotic in the Insane.—Dr. J. Percy Wade, of Catonsville, Md., contributes an article on this subject to the April number of the American Journal of Insanity, in which he remarks that chlorobrom is a mixture of the simplest description, containing thirty grains each of chloralamide and potassium bromide to an ounce of water. The solution was first used, he says, by Dr. Charteris in seaseickness, for which it is said to be an excellent remedy, owing to its hypnotic action. The drug is said to have less action upon the heart and upon the blood-vessels than chloral, and, although depressing to the circulation and the heart, is probably less so than the bromides or other allied drugs. It is less disagreeable to take than paraldehyde, which is often followed by lassitude, headache, or sickness in the morning. Chlorobrom, on the other hand, is not very disagreeable to take, and it leaves no ill effects.

Dr. Keay, says the author, has used the drug with good results, and he recommends it highly in melancholia, especially active melancholia, or brain exhaustion from overwork, and for worried business men, when insomnia is the most serious symptom to combat. In mania, general paresis, and the excitement of epilepsy he has found the drug not suitable, and prefers sulphonal or trional. He administers an ounce of the solution an hour before bedtime, and if the excitement is great he increases the dose from an ounce and a half to two ounces with perfect safety.

The time required for the drug to act, says Dr. Wade, is probably longer than for paraldehyde or sulphonal, for it takes, in mania, about three quarters of an hour to produce sleep, and in melancholia an hour. The sleep is quiet and peaceful, lasting, on an average, five hours and a half. In one case the patient, who was noisy and refused to remain in bed, was given a dose of paraldehyde, but it was immediately vomited. After the vomiting had subsided an ounce of chlorobrom was given and the patient became quiet in fifteen minutes and fell asleep in forty-five minutes, and remained so for four hours. In another case of recurrent mania, when the patient was quiescent and there was inability to sleep, chlorobrom was given with excellent results, and it apparently reduced the length of the attack, the former attack having lasted for four months, while the latter, under the influence of the chlorobrom, lasted for six weeks only.

Dr. Wade’s experience with the drug in simple and in active melancholia confirms Dr. Keay’s report; but in acute mania, notwithstanding Dr. Keay’s statement, he has found that the drug produced sleep, although it took somewhat longer to act; and the sleep, he says, was as refreshing as that produced by other hypnotics. It was administered ninety-six times to sixteen patients, including three with acute mania, three with melancholia, seven with dementia, and one each with active melancholia, epilepsy, and periodic mania. The dose was an ounce, as a rule; and was found to be sufficient to produce sleep in most cases.

Dr. Wade says that he has not been able to test the action of the drug in general paresis, and that there seems to be some doubt as to its action in that disease. He thinks it is justifiable to state, as Dr. Keay has done, that chlorobrom is a safe and reliable addition to the small list of hypnotics; that it is most favorable in melancholia, especially of the milder type, and that in acute mania its action is fully as reliable and lasting as that of any other hypnotic we possess.

**Sulphurous Deposits on the Cannulas and Tubes used in Tracheotomy and Intubation.**—The Journal de clinique et de thérapeutique infantiles publishes an article by M. Cochinal, who writes that in the pulmonary complications of diphtheria the breath is very often fetid and all who come near the patient have been able to observe that the cannulas and the tubes introduced into the trachea were covered with a distinctly black deposit. This deposit was seen on the silver cannulas as well as on the metallic tubes employed in intubation. Acting on M. Variot’s advice, the author made an analysis of the composition of this black deposit and found that it was formed by a sulphide.

Through a small apparatus zinc and diluted hydrochloric acid were introduced, and it was ascertained that the gas which was set free had no action on paper saturated with sugar of lead. Then the author added the blackened cannula, and immediately the test paper assumed the brown tint of lead sulphide. The expiration evidently furnisbed, he says, gases containing sulphur products, but these did not exist except in a very small proportion, for the black tint scarcely appeared except at the end of two or three days, save in some exceptional cases where it was manifested after twenty-four hours.

It will be very interesting, says M. Cochinal, to be able to determine in an exact manner the quantity and the nature of the sulphur compounds thus produced, although it will be very difficult to subject a sick child to the very troublesome application of a mask provided with tubes intended to collect the expired products, when the child needs a large space to effect its respiratory acts.

**The Ohio State Medical Society.**—The semi-centennial meeting will be held at Columbus on May 15th, 16th, and 17th, under the presidency of Dr. D. N. Kinsman, of Columbus. The programme includes the following papers: The Physician—A Civic Factor, by Dr. W. S. Phillips, of Belle Centre; The Antitoxine Treatment of Diphtheria, by Dr. W. T. Howard, of Cleveland; A Clinical Report on the Epidemic at Ashambula, by Dr. F. D. Case, of Ashambula; A Demonstration of Technique of Culture Tests, by Dr. A. P. Olmhofer, of Cleveland; Fracture of the Skull, by Dr. E. C. Brush, of Zanesville; Fractions of the Base of the Skull, with Special Reference to Eye Complications, by Dr. C. W. Taughman, of Cincinnati; Dermatology: its Scope, Evolution, and Present Status, by Dr. William T. Corlett, of Cleveland; Deafness from Intra nasal Disease, by Dr. J. A. Thompson, of Cincinnati; The State’s Care of Dipsomaniacs, by Dr. Chauncey P. Landon, of Columbus; The Pathology, Diagnosis, and Treatment of Malaria (illustrated by lantern slides and microscopical demonstration), by Dr. Judson Daland, of Philadelphia; The Complications and Sequelloe of Epidemic Influenza (La Grippe) and Their Epiophysics, by Dr. A. B. Hewetsen, of St. Clairs ville; The Surgical Conception of Peritonitis, by Dr. C. N. Smith, of Toledo; Cervical Adenoma, by Dr. W. J. Means, of Columbus; The Treatment of Pneumonia, by Dr. Joseph Eichberg, of Cincinnati; The Early Recognition of Cancer of the Cervix, by Dr. Hunter Robb, of Cleveland; Report of a Case, by Dr. Thaddeus A. Renny, of Cincinnati; Cancer of the Breast: Remarks on the Pathology and Treatment, by Dr. J. C. Oliver, of Cincinnati; The Vaginal Route for Operations on the Pelvic Viscera, by Dr. D. Tod Gilliam, of Columbus; Meningitis as a Complication of Otitis Media, with a Report of a Case, by Dr. E. S. Allen, of Cincinnati; Circumscribed Thoracic Empyema, by
Dr. George A. Collamore, of Toledo; Uterine Reflexes, by Dr. W. H. Hunnius, of Cleveland; Is this Leprosy? (with presentation of two cases), by Dr. J. G. McDougall, of New Lexington; Medicina (poem), by Dr. W. S. Battles, of Shreve; Eunuchism of the Appendix, by Dr. C. S. Hamilton, of Columbus; Epistaxis in Most Severe Forms: With Reports of Cases, by Dr. Max Thomor, of Cincinnati; The Value of So-called Local Treatment, by Dr. J. F. Baldwin, of Columbus; Systematic Dissemination of Tuberculosis from a Patch of Lupus Vulgaris, by Dr. Robert Peter, of Toledo; A Report on Typhoid Fever, by Dr. John Eliot Woodward, of Youngstown; Some Conditions requiring Special Care after Abdominal Section, by Dr. Rufus B. Hall, of Cincinnati; Acute Intestinal Obstruction Dependent upon Anomalies of the Mesentery, by Dr. N. Stone Scott, of Cleveland; Removal of a Chylous Cyst of the Mesentery, by Dr. T. C. Hoover, of Columbus; Ceciomy for Extra-uterine Pregnancy; Lateral Anomalies by Murphy's Button, by Dr. J. C. Reeve, Jr., of Dayton; Constipation, Ordinary and Extraordinary, by Dr. S. Loving, of Columbus; The Treatment of Malignant Disease of the Rectum, by Dr. George B. Evans, of Dayton; How to Recognize Inipient Insanity, by Dr. A. B. Richardson, of Columbus; Review in Neurology, by Dr. H. S. Upson, of Cleveland; Neural Infixation, by Dr. R. Harvey Reed, of Columbus; The Prognosis of Paralysis, by Dr. Phillip Zemmer, of Cincinnati; Remittent Miasmatic Paralysis, by Dr. James Macready, of Monroe; Spondylitis vs. Sciolosis, by Dr. S. L. McCurdy, of Pittsburgh; The Electrical Treatment of Facial Blemishes, by Dr. O. Hasencamp, of Toledo; Some of the Pathological Conditions of the Nose Severely Affecting the Eye, by Dr. W. A. Melick, of Zanesville; The Influence of Antiseptics on Modern Cataract Extraction, by Dr. C. F. Chirke, of Columbus; Tuberculosis in the Light of History, by Dr. H. H. Spier, of Ravenna; The Nature of the Organ and the Nature of the Conditions as Factors in the Ætiology of Tuberculosis, by Dr. Elh Conn, of Akron; A Plea for a State Hospital for Crippled and Deformed Children and for those of Defective Sight and Hearing, by Dr. S. S. Gray, of Piqua; A Report of Two Cases of General Gaseous Empysema of the Body after Death in Typhoid Fever, with exhibition of specimens, by Dr. W. T. Howard, of Cleveland; Cases Illustrating the Radical Cure of Inginal, Femoral, and Ventral Hernia by the Author's Operation, by Dr. C. A. L. Shields, of Cincinnati.

The American Microscopical Society.—The next meeting will be held at Cornell University, in Ithaca, N. Y., on August 21, 22, and 23, 1895—that is, during the week before that of the meeting of the American Association for the Advancement of Science, which is to be held in Springfield, Mass. Ithaca is as central a point as can be found for the meeting. It is connected with the great trunk lines in such a way as to make it very readily accessible by railroad. The unsurpassed beauty of the region and the richness of both its terrestrial and aquatic fauna and flora make Ithaca an ideal place for holding the meeting. It is equally attractive to students of natural history and to those who love beautiful scenery. The facilities of the university and its equipment for carrying on microscopical work must add to the attractiveness of Ithaca as a place of meeting. In most of the scientific departments of the university there are already members of the society, and in all departments, we are assured, there will be a most hearty welcome, and every reasonable aid will be furnished for the success of the meeting. The president of the university, Dr. Schurman, extends to the society a most cordial welcome. The university buildings, which will be at the disposal of the society, are especially adapted for the formal presentation of papers, blackboard illustrations, hanging of diagrams, etc., as well as for any demonstration that authors may desire to make. Besides the attraction of papers and demonstrations by members, nearly all the opticians have expressed not only a willingness but a desire to be present and make an exhibit of their microscopes and microscopical apparatus, thereby affording the members an opportunity to see all the new and standard apparatus. A special feature of the meeting will be the setting apart of one or more sessions for the reading of papers on methods and the demonstration of special or new methods. The chairman of the local committee, Professor W. W. Rowl, or the president, Professor Simon H. Gage, will be glad to receive requests from those who desire to have some specially difficult method or structure elucidated, and an effort will be made to get some member particularly expert in such subject to demonstrate it before the society. President Gage's enthusiasm in behalf of this meeting will guarantee a profitable time to all who come. The opportunity to observe his methods in his own laboratory is a privilege none could afford to lose even if there were no other attractions.

The New York Academy of Medicine.—At the last general meeting, on Thursday evening, the 2d inst., the special order was a memorial service in remembrance of the late Dr. Alfred L. Loomis at which addresses were to be read by Dr. Lewis A. Stimson, the Rev. Henry M. MacCracken, and the Hon. Abram S. Hewitt.

At the next meeting of the Section in Pediatrics, on Thursday evening, the 9th inst., the following papers will be read: What is Croup? by Dr. S. Henry Dessa; A Report of Intubation Cases, by Dr. F. M. Warner; The Treatment of Group by Colonel Subscriptions, by Dr. J. Henry Furtinett; and A Board of Health Bulletin on Prevention of Disease among Infants, with the presentation of a new pasteurizer, by Dr. Henry L. Cott.

At the next meeting of the Section in General Surgery, on Monday evening, the 12th inst., a paper entitled Repair after a Bone-flap Operation on the Skull will be read by Dr. George Woolsey, and one on The Use of Torsion instead of Ligatures, by Dr. John F. Erdmann. Patients will be presented and pathological specimens, new instruments, and apparatus exhibited.

The Harlem Medical Association of the City of New York.—At the eighth regular meeting, on Wednesday evening, the 1st inst., the following papers were to be read: The Use of Trial Lenses in Doubtful Cases of Asthenopia, by Dr. W. E. Chase; Iritis—Diagnosis and Treatment, by Dr. George H. Cocks; and The Significance and Value of the Knee-jerk in Diagnosis, by Dr. W. M. Leszynsky.

The New York Medico-surgical Society.—At the next regular monthly meeting, to be held on Monday evening, the 6th inst., the following papers will be read: The Pathology of the Tuberose, relative to the Lung, by Dr. Joseph Mair; and Hysterical Amnesia—a Report of Four Cases Treated by Hypnotism, by Dr. J. Arthur Booth. New instruments will be exhibited.

A College Hospital for Infectious Diseases.—It is announced that such a hospital is to be established in connection with Yale University.

The Death of Dr. Carl Thiersch, of Leipzig, professor of surgery in the University of Leipsic, is reported to have taken place on Sunday, April 28th.
Original Communications.

THE DIAGNOSIS OF LESIONS OF THE LUMBAR CORD, CAUDA EQUINA, AND CONUS MEDULLARIS.*

By FREDERICK PETERSON, M. D.,
CHIEF OF CLINIC, NERVOUS DEPARTMENT, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

As an evidence of the progress of neurological science of late years, there is perhaps nothing more interesting than the unraveling of the mysteries of the tracts and centers and nerve trunks of the lower part of the spinal cord. We are now in a position to make very accurate diagnoses of the nature and position of lesions in the lower part of the spinal canal from a study of the peculiar distribution of anesthetics, the extent and character of paralyses, and the disturbances of various reflexes. Then, too, lesions in this part of the organism, such as caries, spinal injuries, hemorhages, and neoplasms, are not so rare but that a brief exposition of the points of differential diagnosis should be of service to every physician.

The lumbar enlargement of the cord lies in the spinal canal opposite to the space between the lower portions of the tips of the tenth dorsal and first lumbar spines. Thus the spinal canal is twenty-six to twenty-eight inches long, and the spinal cord is only seventeen or eighteen inches long. The remaining space of nine or ten inches of the canal is occupied by the cauda equina, composed of the lumbo-sacral nerve trunks coming off from the lumbar enlargement of the cord. The termination of the cord at the lower border of the first lumbar vertebra is not always kept sufficiently distinct in the mind of the student or physician. I have seen, for instance, a physician seeking for cord symptoms in a fracture of one of the lower lumbar vertebrae.

The lumbar enlargement of the cord has in its anterior horns the trophic centers for all of the muscles of the lower extremities. Into it pass all the sensory fibers from the lower extremities, genitals, rectum, and nates. In it are the reflex centers for such important reflexes as the knee-jerk, ankle-clonus, cremasteric, plantar, and gluteal reflexes. And here, too, are the centers for the sphincters of the bladder and rectum, and for erection, menstruation, and parturition.

These various organs and functions are represented serially in the segments which constitute the lumbar enlargement, five lumbar and five sacral segments. The centers for the lowest muscles of the lower extremities in the lower segments of this enlargement, and the higher the situation of the muscles in these extremities the higher the representation in the segments. There is also a segmental sensory distribution, only the areas of sensibility run lengthwise down the extremities, and require special study in order to appreciate their relations to the nerve trunks and segments of the cord. The diagram submitted will be helpful to this end.

Thus destructive lesion of the fourth and fifth sacral segments causes anesthesia of the perineum, posterior surface of the penis, scrotum, rectum, and vagina. At the third sacral segment this area is extended out over the buttocks and downward on the backs of the thighs, so that the area corresponds to that touched when seated in a saddle. The higher the lesion the greater the extent of this anesthesia. The peculiarities of this distribution are noted in the diagram. The reflexes have their particular segmental centers. Thus of the very important ones, the knee-jerk center is in the third lumbar segment, the ankle-clonus in the fifth lumbar segment, the cremasteric in the three upper lumbar.

* Read before the Hospital Graduates' Club, February 28, 1895.
and the bladder and rectum in the lowest point of the cord, in the fourth and fifth sacral segments and the conus. By some authorities this club-shaped tip of the cord, the conus medullaris or conus terminalis, is supposed to be exclusively the center for the vesical and rectal reflexes, though this is not proved.

We must remember, in this consideration of the segmental arrangement of the muscles, reflexes, and so on, in the lumbar cord, that there are also in the lateral columns fibers coming down from the brain which convey motor impulses from above to the muscles and which also inhibit the reflexes. Thus a lesion in the second lumbar segment might exaggerate the knee-jerk and cause ankle-clonus, because of the inhibitory fibers to these centers being affected. On the other hand, a lesion in the third lumbar segment may give us the very singular phenomenon of lost knee-jerks in conjunction with ankle-clonus.

Now, the cauda equina is composed chiefly of the great nerve trunks arising from this lumbar enlargement, one pair from each segment, and hence each pair of nerves represents the motor, trophic, sensory, and reflex functions of the segment from which it springs. Any lesion of them must necessarily cause much the same effects as would arise from lesions of the segments from which they come. Thus lesions affecting the sacral nerve roots produce the same anaesthetic areas as do lesions of the sacral part of the cord, together with paralysis of the bladder and rectum. A lack of symmetry on the two sides in the distribution of the paralyses and the anaesthetic areas would be, however, presumptive of a cauda rather than a cord lesion. An exceedingly slow and irregular development of the symptoms would also suggest a cauda lesion. But it is not always easy to distinguish cauda from spinal-cord lesions, and the fact must be borne in mind that often both the cauda and the lower part of the cord are involved together in the pathological process.

It has been demonstrated that pressure on the cauda equina affects to a greater degree the nerves in the middle of the cauda than those near the surface (Thorburn). The lower nerve roots of the cauda are nearer the middle line than the nerves which pass out above them; and when pressure is brought to bear upon the cauda, the nerves which pass out at the lower level are more seriously affected than those emerging above them.

In lesions such as hemorrhage or compression, where improvement may take place, the upper roots are apt to show signs of a change for the better sooner, and may indeed recover completely, while the lower ones remain as before.

Pressure upon the nerves of the cauda is often sufficient to produce widespread paralysis when sensation is but slightly affected (Starr). This is often of value in a differential diagnosis, since lesions of the same magnitude in the lumbar enlargement would produce only a moderate amount of paralysis, depending upon the segment or segments involved.

In traumatic conditions the external evidence of fracture below the first lumbar vertebra, affecting the lumbar or sacral portions of the spinal column, would be an important indication of involvement of the cauda equina.

Pain and tenderness over the lumbo-sacral regions have been noted in some of the cases of lesions of the cauda equina, such as neoplasms. The pain is nearly always chiefly sacral.

In cauda lesions the sciatic and pudic and sometimes the anterior crural and obturator nerves are particularly apt to suffer. Whether the degenerative reaction in the muscles supplied by the affected nerves will be present depends naturally upon the amount of damage done to them, which is variable.

As to the reflexes, the knee-jerks will be absent if the nerves to the anterior thigh muscles are affected. In no case of purely caudal lesion will they be exaggerated. The plantar reflexes are usually absent. The extent of the lesion in the cauda will determine to what degree the sphincters are disturbed. Disorder of the mechanism governing the sphincters of the bladder and rectum will depend upon whether their particular nerves are involved and to what degree. Urinary retention with overflow incontinence is not very frequent in cauda lesion, and when it does exist may be recovered from as pressure diminishes. The presence of complete paralysis of the bladder and rectum is rather suggestive of coincident lesion of the lower tip of the cord.

Bedsores, and sometimes perforating ulcers, occur in a certain number of cases of cauda lesion.

In some instances it may be necessary to differentiate peripheral nerve lesions, such as multiple neuritis and disorders of the lumbar and sacral plexuses. Ordinary multiple neuritis presents no difficulty, but a bilateral lumbo-sacral neuritis may offer obstacles in the way of diagnosis for some time until absolutely characteristic symptoms have appeared. In other lumbo-sacral plexus lesions a bilateral manifestation of symptoms should form a diagnosis of cauda disorder, though in some very rare instances the cauda lesion may involve but one side and thus give rise to confusion.

Occasionally a lesion of the cauda (tumor) may for a time simulate locomotor ataxia by presenting some of the symptoms common to both—viz., loss of knee-jerks, disorder of the bladder sphincter, sharp pains radiating down the legs, and peculiarity of gait. But there will be no ataxia, and papillary symptoms will be wanting, while atrophies and anesthesias are almost certain to develop in the course of time and thus demonstrate the presence of a cauda lesion.

The most common of all lesions affecting the cauda is fracture and dislocation of the lumbar spine, compressing or crushing the nerve roots, or both. Moderate dislocation of the vertebra may cause little damage, because of the large size of the canal and the small part of it occupied by the nerves. The symptoms will vary with the extent and degree of the injury. Hemorrhage is another though infrequent lesion of the cauda equina. Much more common than this are neoplasms. Among the tumors which have been described as developing in this part of the vertebral canal and affecting the cauda equina are sarcoma, fibrosarcoma, meningocle in spina bifida, gumma, cavernous angioma, and multiple neuromata.
The chief characteristics of tumor compression of the cauda equina are slow and progressive development of the atrophic paralyses, reflex disorders and anesthesias peculiar to the region, and intense and increasing sacral pain of a radiating character, and sacral tenderness. Sometimes retrogression may take place, or the growth be temporarily arrested.

As regards isolated lesions of the conus medullaris, it has become current in neurological literature to a certain extent that we have from such complete paralysis of the bladder and rectum. This would mean that the vesical and rectal reflex centers then were situated wholly in the conus. But, as far as I can learn from a careful search of the literature, this current idea is based upon two cases reported respectively by Oppenheim and Lochmann. Oppenheim (Arch. f. Psych., xx, 1889, p. 298) has a paper Uber eine sich auf den Conus Terminalis des Rückenmarks beschränkende traumatische Erkrankung; but, on reading his paper and the result of the autopsy, I find it is not at all a case of "traumatic disease limited to the conus terminalis," for he describes how the changes become less marked in the sacral portion of the cord, and still less so in the lumbar portion. Lochmann's case, too, is not wholly satisfactory in this respect.

THE SIGNIFICANCE OF EYE SYMPTOMS IN KIDNEY DISEASE,
WITH SOME REMARKS ON THE NECESSITY OF A MORE RIGID ENFORCEMENT OF THE LAWS REGULATING MEDICAL PRACTICE.*

By FRANK VAN FLEET, M.D.,
OPHTHALMIC SURGEON TO RANDALL'S ISLAND SCHOOLS AND HOSPITALS; ASSISTANT SURGEON TO MANHATTAN EYE AND EAR HOSPITAL; INSTRUCTOR IN DISEASES OF THE EYE
AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The saying that familiarity breeds contempt does not apply to the science of medicine, for, when one has acquired the necessary knowledge to make him familiar with his subject, that knowledge fills him with the profoundest respect for his calling. In fact, not only does one not feel contempt, but is prone to magnify its importance; indeed, ever since the days of specialties we find each specialist magnifying his subject as if he thought it of greater importance than anything else in the world. Familiarity with the specialist may breed contempt for him, but never for his subject. I am not an enthusiast, yet I should like to impress on you the importance of the subject I present for your consideration to-night, and when I have finished I desire your free discussion.

The eye presents many features, owing to its peculiar function, that permit of a closer examination during life than any other organ of the body. We have in the back of the eye an expanded nerve between which and the outer air only transparent media intervene, in consequence of which a glance through these media is like looking through glass; the exposed end of the optic nerve can be seen, together with its expansion into the retina and its blood-vessels; changes here can be studied positively during life, that, situated in other parts of the body, can only be appreciated by the subjective symptoms their presence occasions.

Considering, therefore, that changes in nervous tissue and blood-vessels are, very often, the first evidences of constitutional disease, we see at once how important these facts are.

Nephritie disease influences the eye externally and internally; the external manifestations, such as edema of the eyelids and ocular conjunctiva, possess no special significance, and do not, as a rule, attract attention until after edema in other parts of the body, together with other symptoms, have demonstrated the actual seat of disease. In fact, edema of these parts, occurring independent of edema elsewhere, would point to cardiac rather than to renal disease. There is, however, a symptom that occasionally occurs which is external to the eye, and which of itself, although I have never seen it exist in this connection without deeper trouble being also present, may be the first to attract attention. I refer to subconjunctival hemorrhage. I have seen several cases of this kind, the last being only a short time ago.

A gentleman called at my office with several small circumscribed hemmorhages, none of which were more than one millimetre or two millimetres in diameter, situated on both sides of the cornea in each eye. An ophthalmoscopic examination revealed retinitis albuminurica, and a further investigation disclosed the existence of chronic Bright's disease. These hemorrhages became absorbed in the course of a few weeks and no fresh ones occurred. In this case, although a careful interrogation elicited a story which made it plain that renal trouble had existed for more than a year, and which has since terminated in death, yet the subconjunctival hemorrhage was the first symptom to cause the patient to seek medical advice.

There is really no reason why subconjunctival hemorrhage should not occur in this connection, as well as hemorrhages elsewhere, oftener than it does, but I believe that as a clinical phenomenon of Bright's disease it is rare. Of the text-books on diseases of the eye but one, to my knowledge, contains any mention of it.* Its significance is serious.

There are no other external conditions of the eye that occur as the result of Bright's disease, nor do we find any change in the interior until we get to the back of the organ, and the changes here found affect the blood-vessels and nerve. These changes are optic neuritis, retinitis, and neuroretinitis, when affecting the nervous tissue, and hemorrhage when affecting the blood-vessels.

It must be admitted that affections of the optic nerve and retina do not permit of a sharp line of demarcation being drawn in every instance, and an inquiry into the relations these two structures bear to each other will demonstrate why this is so.

After the deceasement of the optic tracts in the chiasm the optic nerves continue on, one on each side, pass through the optic foramina into the orbits, and thence

until they reach the posterior surface of the eye. The cranial portion—i. e., the portion between the chiasm and foramen—has but one covering, the pia mater of the brain, while the orbital portion, that lying between the foramen and the eyeball, has three—the pia mater, the arachnoid, and the dura mater.* These coverings become part of the sclerotic coat on reaching the eye, and the fibers going to make up the nerve, losing their medullary sheaths, pierce the eye as axis cylinders only, and, spreading out over its interior, reach the most anterior portion of the globe, forming the retina. The retina, composed as it is of different layers, is made up of nerve elements and connective tissue. Different functions have been given to these different layers, it is true, and descriptive works on the eye give these ten layers separately and in detail; they are, nevertheless, simply the expansion of the axis cylinders of the optic nerve peculiarly modified and arranged because of the functions they have to perform, and bound together with connective tissue and a granular matter of unknown function. It is therefore impossible to say that inflammation exists in one part independent of the other. For the sake of convenience, however, we speak of inflammations of these parts as neuritis, retinitis, and neuro-retinitis.

Severe optic neuritis, uncomplicated with marked retinitis, is seldom due to nephritic trouble. Indeed, as a rule, it seems to be secondary to the retinal inflammation when happening in this connection; yet we would not feel, even in a case of simple neuritis, that we had inquired fully into the cause until an examination of the urine had been made. I believe that a number of cases of mild attacks of optic neuritis, the origin of which may seem doubtful, will have much light thrown on them by repeated examinations of the urine. At least, such has been my experience. It has often seemed to me also that, if repeated ophthalmoscopic examinations were made in patients with kidney disease, we might frequently find inflammations of the optic nerve.

Inflammation of the optic nerve may exist without any impairment of vision, and not infrequently patients apply to oculists for the relief of headaches, dizziness, etc., when a careful examination fails to reveal any refractive trouble, but the ophthalmoscope, showing optic neuritis, discloses for the first time the cause of the symptoms to be uremic poisoning.

The most frequent and by far the most disastrous form of inflammation attacking the eyes as the result of kidney trouble is retinitis albuminurica. Optic neuritis may subside, leaving little or no evidence of trouble having existed; atrophy may result, but not of necessity. Retinitis albuminurica, on the other hand, seldom disappears without leaving its marks.

As we may find the only existing complication to be a mild neuritis, so may we also find in a few cases only a simple inflammation of the retina, characterized by a slightly hazy appearance of the fundus as viewed through the ophthalmoscope; what we most often find, however, is the retina engorged with blood, the nerve perhaps more or less swollen, the fundus plentifully besprinkled with white patches, looking, to use a borrowed expression, as if white paint had been spattered from a brush on the red background.* There is no regularity about the distribution of these spots, excepting at the macula, where they tend to assume a stellate appearance, or are grouped in radiating lines about the fovea centralis.

Taking, then, a fundus, the nerve more or less dendred and perhaps swollen, the retina congested and marked indiscriminately with the white patches, while here and there, in greater or less profusion, are found hemorraghes varying in size from mere points to those as large as a split pea or larger, and we have presented to the observer a condition that causes him to at once think of the kidneys. True, this condition of the eye is found complicating other affections than renal—glycosuria and also some forms of cerebral disease—but in the majority of cases retinitis albuminurica is the closing chapter in Bright's disease and means death. I have qualified this statement by saying in the majority of cases, and while in my experience its occurrence with chronic Bright's does mean death, from which there is no escape, and the termination in which can be predicted with some degree of certainty as regards time, yet there is a chance when it occurs in acute kidney disease—although its occurrence in this connection is of the gravest significance—of saving life. But a favorable termination, even in acute disease, requires the most vigorous treatment. It may safely be said that retinitis albuminurica occurring as a complication or sequel in the course of either acute or chronic renal trouble is of the gravest significance. In the past twenty-two months I have had in my private practice six cases of retinitis albuminurica, not associated with pregnancy, of whom all but one have since died, and, strange as it may seem, not one of these six people knew that he had renal disease. Two were sent to me by physicians who had met them socially, and who suspected that the patients might have some cerebral trouble; one came with his daughter and thought it would be well to have his eyes examined; and the remaining three came of their own volition after fruitless journeys to opticians in town trying to get glasses for the relief of headaches or, as in one case, failing vision.

Chronic Bright's disease of the kidneys, as we all know, is a most insidious affection, creeping upon its victim, who is often unaware of its existence until some serious warning in the shape of eye symptoms or a convulsion calls attention too late to the fact that the little headaches, the dragging, lazy feelings and trifling aches of the past were due to the same cause.

In addition to the inflammatory conditions affecting the back of the eye as the result of kidney disease, we have also hemorraghes, which are not apparently due to either neuritis or retinitis. This is a condition analogous to apoplexy and due to a weakened or diseased condition of the blood-vessels occasioned by the deficient elimination of deleterious material from the blood. The same thing

can occur as the result of rheumatism or gout, or any influence capable of producing changes in the walls of the blood-vessels. We may have, either as cause or effect, inflammation of the retina; hence the terms used to designate this condition, as retinitis hemorrhagica, retinitis apoplectic, etc. Hemorrhage into the retina as a result of atheroma of the vessels in old age is a grave condition, inasmuch as it often precedes cerebral hemorrhage from the same cause. So also retinal hemorrhage occurring as the result of diseased blood-vessels in nephritis. In chronic nephritis it is a fatal symptom. It is of much greater significance than if it is the result of rheumatism or gout, for these two affections, although the external manifestation of deficient elimination, do not of necessity imply disease of any particular organ, and measures directed to the eliminative organs of the body generally, as the skin, bowels, etc., may rid the patient of this effete material, and corrected habits of life prevent its return. When, however, the poison is urea and the cause of its presence is structural change in the kidneys, the outcome, as before stated, can be predicted with certainty. Vicarious elimination under these circumstances will not subserve the same purpose for any considerable time. There has not been in my experience a more distressing incident than that which I have been called upon to witness in a number of cases, to wit: A man of forty or fifty years, with a growing family dependent on him, presents himself after he has been journeying about, for periods varying from six months to a year or longer, to the numerous so-called "refracting opticians," for the relief of headache, dizziness, etc., sometimes, too, on the advice of his family physician, and to find on examination a trifling refractive error, easily remedied, but in addition retinitis albuminurica, or hemorrhages in the fundus, which further examination shows to be due to chronic Bright's disease. In a very short time—two years or less—this man will be dead. Still another symptom occurs in connection with kidney trouble, the pathology of which is not fully understood. I refer to anemia or nephritis. In this condition sudden and complete blindness occurs without any apparent change in the eye itself, and is the result of the action of urea on the visual centers, the generally accepted belief being that it is due to cerebral anemia. Be this as it may, while it is a grave symptom, its effect on vision is only temporary, and its occurrence is not followed by the same fatality that follows retinitis. It occurs most often in acute disease and admits of complete recovery. Cases have been reported where the two conditions—retinitis albuminurica and anamnisis nephritis—have co-existed, and here, of course, the prognosis would be different.

We have, then, two classes of symptoms manifesting themselves in the eye, both indicative of kidney trouble; one coexisting with structural changes in the eye-ground, characterized by inflammation, fatty degeneration of nerve tissue, and hemorrhages, which, should the patient survive, subsides with more or less atrophy, leaving defective vision; the other, characterized by sudden and complete blindness, without structural change, subsides without affecting vision. The first, when occurring in acute kidney disease, and especially in the progress of the exanthemata and in preg-

nancy, may recover completely; but, happening in the course of chronic kidney disease, of whatever variety, means in the majority of cases—say, eighty per cent.—death within two years.

And now in this connection let us consider two cases that have presented themselves to me within the past few months, from which we can learn a lesson.

Case I.—Mr. N., aged forty-nine years, came to my office, August 22, 1894, with his daughter, who was under treatment for refractory trouble. Mr. N. had worn glasses for two or three years, but of late had had a most uncomfortable feeling in his head, and the opticians to whom he had applied had changed his glasses several times without giving him relief, until now he thought he had better have his eyes examined. My notes are as follows: Patient, a large, portly man, looking very robust, complains of headache and dizziness. Smokes and drinks excessively. Vision = 7/7; accepts no glass. Read Jaeger i from 8 to 20 inches with +2 D. S. Ophthalmoscopic examination: Eight eye, nerve grayish and swollen. Several small hemorrhages scattered over fundus. Along the blood-vessel, extending downward and outward about two disc diameters from the nerve, is a large hemorrhage and a large white plaque such as we find in retinitis albuminurica. Macular region unaffected. Left eye normal.

August 25th.—Same characteristic appearance near macula in left eye. Referred with note to family physician, Dr. K., with serious prognosis. Dr. K. reports: Urine, specific gravity, 1:044; quantity large, and abundance of albumin.

September 9th.—Vision still 7/7.

16th.—Vision 7/7. Still complains of headache. No new hemorrhages, but marked neuritis in both eyes. Characteristic white plaques in left eye.

I did not see this patient again, but under date of April 5, 1895, Dr. K. writes me as follows:

"Dear Dr. Van Fleet: I am glad to be able to answer your question in the affirmative. I had written to ask if Mr. N. was still alive. I rarely see Mr. N. now, and only occasionally do I find albumin in his urine in quantity, although he always complains of his heart. Very truly yours,

"M. R. R."

I do not imagine that the patient had had his ocular trouble long when I saw him in August, 1894. At least there was no marked change in his fundus, and active treatment has improved his renal defect. I have not seen him since September, a period of seven months, and I can not say what the condition of his eye-ground may be at present, but, considering the fact that he has chronic Bright's, and that his heart troubles him, which, I take it, means that it no longer compensates, and I venture to predict that the rule will hold good in his case—the rule being, as before stated, that in the majority of cases the occurrence of retinitis albuminurica in the course of chronic kidney disease means death in two years or less. I sincerely hope that Mr. N. will prove the rule by being an exception.

In contrast with the above I will narrate a second and more recent case:

Case II.—Mr. H., aged forty-two years. Headache for past two years. A year ago, while taking his annual vacation deer-shooting in the Adirondacks, he noticed that his vision was not as acute as formerly. On his return to town he consulted an optician, who prescribed glasses. After the first optician had changed his glasses several times, he consulted a second, then a
third, and, after a journey about the city, visiting a number of opticians in the course of the year, he finally consulted an oculist. Examination revealed defective vision equaling 2%, marked neuroretinitis albuminurica, with profuse hemorrhages. I referred him to his family physician, who, after an examination of his urine, instituted vigorous treatment. I saw the patient several times after this, but was unable to note any change in the ocular condition. On March 22, 1885, four months after his first visit to me, while doing his ordinary work, the patient was seized with a convolution and died in about an hour.

Retinitis albuminurica, or any affection of the eye due to renal disease, indicates that the body is saturated with urea, and clinical experience has taught us that death is imminent. Yet, notwithstanding its grave import, we must not lose sight of the fact that a few cases do end in recovery. Life may be saved, but the changes that have taken place in the eye leave their marks. Occurring at the macular region, where usually vision is most perfect, these changes will most certainly leave impaired vision, perhaps blindness. Obviously, if vision is to be saved and life prolonged, it is necessary that the condition should be recognized early in its course and appropriate treatment inaugurated. Spectacles may cure many reflex phenomena, but Bright's disease is not one of them. And yet, in the face of these terrible consequences, we allow to go on in our city without challenge a most iniquitous system, an openly advertised violation of the law.

From the district attorney of the city and county of New York I learn "that the laws regulating the practice of medicine in this city are rather complicated and in an uncertain condition," which, if true, is a deplorable condition of affairs, and, in view of the fact that we live in an advanced age, that we spend large sums of money in support of law-making and law-interpreting machines, and that privileges of medical practice placed in the hands of charlatans and quacks entail on the two million inhabitants of this great metropolis untold misery, suffering, and death, is a crying outrage.

I believe the fact to be that there are laws enough, but that they are not efficiently managed. The law tells who shall practice medicine and provides for the punishment of violators thereof. Druggists have been punished for counter prescribing, but no attention has thus far been given to opticians practicing illegally. Objection may be urged that opticians in giving glasses are not practicing medicine, but the objection is not tenable. Let us suppose two illustrations: A person goes to a druggist and says, "I am suffering from shortness of breath which I think is due to heart trouble." The druggist listens to the patient's heart, tells him that he has heart trouble, and prescribes digitalis or some other remedy. He would undoubtedly render himself liable for violation of the laws governing medical practice.

Let us consider the second illustration: A person goes to an optician. He may have Bright's disease, he may have some incipient nervous trouble, but he says to the optician, "I suffer from headache, dizziness, fullness in the head, and a long list of symptoms, and I think my eyes are at fault." The optician examines his eyes and gives him glasses. Is he not practicing medicine illegally? The druggist may be as capable as a physician to listen to the person's heart and to give the proper dose of digitalis; but the druggist has not had the training necessary to enable him to judge of the possible connection between the shortness of breath and the heart lesion, and he may or may not give the proper remedy. The same applies to the optician; the work required in this connection does not consist in the successive placing before a patient's eyes of a series of lenses, in order to ascertain which lens gives the best vision. It requires a knowledge not only of optics, but of medicine as well, to arrive at a proper conclusion of the relation of cause and effect. It may be true that in a given case the trouble is due to a refractive error easily relieved with glasses, yet, even so, this subject is one of growing importance, and requires of the practitioner a knowledge that can only be obtained, as in all other branches of medicine, by careful and painstaking clinical research. The importance of this department may be better appreciated when we consider that of the 10,319 eye patients who applied for treatment at the Manhattan Eye and Ear Hospital in 1893, 32.18 per cent, were cases requiring glasses, and for the year ending September 30, 1894, out of 11,291 eye patients, the percentage was 34.29 per cent., an increase of over two per cent. When we consider that twenty years ago the percentage of people requiring glasses was twelve per cent. and that now it is over thirty-four per cent, and increasing yearly, we must realize that this is too important a branch of medicine to be in the hands of unskilled and often uneducated opticians. We find in this city unauthorized individuals teaching jewelers how to fit glasses to eyes, giving them a certificate of proficiency after a few months of instructions. Everywhere along the principal avenues we find these certificates displayed in the windows of jewelry stores, accompanied perhaps with the sign "graduate optician," whatever that may mean. So far as I know there is no legally incorporated institution with power to bestow such a title. It surely is a perverted interpretation of the law which does not include these people in the class of violators thereof. When physicians receive in one mail the cards of the professional abortionist, and in the other the advertisement and coupons of the "refracting optician," who not only offers to give you a report of cases you send him, but also as an inducement will "refract" the members of your family at reduced rates or gratis, surely charlatanry runs riot. And yet the prosecuting attorney of the city and county of New York says that "the laws governing medical practice are complicated and uncertain." Certainly the evidence is easily obtained.

Laws made in accordance with the desires of the people and for their benefit are easily enforced, but laws for the benefit of a few individuals can not be, and ought not to be, enforced. It is therefore not wise or just to speak of the rights of the medical profession. We have no rights, no privileges not accorded to other citizens, excepting where exemption from certain duties is accorded us because

* Cohn's statistics.
of the peculiar relations we hold to the public, and in these exemptions the benefit is the benefit to the community. But we are guardians, in a measure, of the public health, and as such should insist on the enactment of laws for public protection, and we should insist also on their enforcement. It should be—indeed I think it is—a criminal offense for any one to prescribe a medicine, a mechanical appliance, or any substance directed to the cure or relief of disease or deformity unless he shall first comply with the laws governing medical practice and be thoroughly qualified.

In conclusion, let me bespeak the co-operation of physicians generally against the "refracting optician," not for the benefit of the oculist, who does fairly well as it is, but for the benefit of the confiding public, which, as the showman remarked, delights in being humbugged. The people have made laws for their protection which at the same time benefit the doctors, and in return have a right to ask that the medical profession see that these laws are enforced.

April 15, 1895.

DOUBlE CASTRATION

FOR HYPERTROPHY OF THE PROSTATE.

A PROTEST.*

By SAMUEL ALEXANDER, M.D.,
Professor of Genito-Urinary Surgery and Syphilis in the Bellevue Hospital Medical College; Surgeon to Bellevue Hospital.

During the past two years two new operations for the relief of enlarged prostate have been suggested, both of these having the same object in view—namely, the removal of the obstruction to urination by causing atrophy of the prostate.

In 1893, Bier, of Vienna, published the results obtained in three cases of prostatic hypertrophy in which he had ligated the internal iliac artery, and Willy Meyer, of this city, has reported the results of three cases in which he performed the same operation. The results of these operators are far from being an encouragement to others to adopt this mode of treatment.

Dr. J. W. White, of Philadelphia, in a paper read before the American Surgical Association in 1893, suggested the possibility of relieving obstructive disease of the prostate by performing double castration. He based his suggestion upon the results of experiments made at his request by Dr. Kirby, of the University of Pennsylvania, upon dogs, which showed that the removal of both testes in these animals was followed by a rapid shrinkage in the size of the prostate. Dr. White in this paper stated that he had not had the courage of his convictions, and advanced the suggestion as a reasonable possibility. In the same year Ramn, of Copenhagen, working independently of White, published an account of a case of prostatic hypertrophy in which he had performed double castration, and in 1894 he reported a second case treated by this method. The publication of Dr. White's paper has attracted much attention and caused considerable criticism. It has been noticed in the principal medical journals both here and abroad.

In a later communication published in the Union médicale Dr. White has reaffirmed his position with more positiveness, and several surgeons during the past year have published the results of cases of prostatic hypertrophy treated by double castration.

I am in possession of facts which lead me to believe that this operation has been performed by other surgeons who have not as yet published their results, and it is likely that its value as a remedial measure will be thoroughly tested. It is difficult to form an accurate estimate of the results that have followed the performance of this operation in the cases thus far reported, but the facts stated in these reports are far from convincing me that the operation is of great value, for the data upon which such an estimate should be based are almost entirely wanting in these reports, as I shall presently show. If the operation is to become recognized as a justifiable method of treatment for the relief of prostatic hypertrophy, it is very important that those who perform it during the period of experimentation should be careful to record fully the facts in each case upon which a true estimate of its value can be based.

Before entering upon a criticism of the present clinical aspect of this operation let me first present a very brief résumé of the principal facts which have been brought out by the discussion of this subject in the journals.

In an article published in the October number of the Annales des maladies des organes génito-urinaires Launois has called attention to the close relationship existing between the development of the prostate and that of the testicle, and has shown that when the development of either testicle is arrested there is a corresponding arrest of development in the prostate upon the same side. This is in agreement with the researches of Godard, published between 1856 and 1860, and it seems probable that in nearly all, if not in all, cases where one of the testes in its descent fails to reach the normal position in the scrotum, the retained gland is smaller and undergoes certain atrophic changes. In those cases of unilateral ectopia the prostate upon the affected side does not enlarge at puberty, and remains small and apparently atrophied. When both testes are retained, either within the abdomen or in the inguinal canal, the entire prostate is undeveloped and is much smaller than normal.

The following cases may be added to those which have been reported by Launois:

CASE I.—Patient, twenty-six years of age, referred to me by Dr. Stafford, of Portchester, N. Y. Right side of the scrotum empty. The testicle can be felt in the right inguinal region as a small tumor, excessively painful. Right side of the prostate one half smaller than the left. Right testicle removed in Bellevue Hospital in April, 1894.

CASE II.—M., thirty-seven years of age, admitted to Bellevue Hospital on December 22, 1894. Scrotal sac empty. A large, soft tumor in right inguinal region, consisting of testicle and omental hernia. In the left inguinal region a very small testicle can be felt just outside the internal ring. The prostate is apparently of about half its normal size. Operation performed on January 25, 1895, upon the right side only. A small, atrophied
testicle was removed, the omental hernia reduced, and the internal ring closed.

It is likewise true that in cases where one or both testes are undeveloped the prostate is not fully developed. Launois quotes such a case reported by Godard, and I have observed the following cases during the past year:

Case I.—W., thirty-two years of age, admitted to Bellevue Hospital on March 19, 1894. Both testes very small, about as large as a those of a boy at puberty. No sexual desire. The prostate in this case was easily recognized by the finger in the rectum, but seemed to be much smaller than normal.

Case II.—Patient, aged thirty-five years, admitted to Bellevue Hospital on December 29, 1894. He had tubercular disease of the left epididymis of fifteen months’ duration. Right testis very small, not larger than a young boy’s. Right side of prostate distinctly smaller than left.

Launois quotes Godard to show that when both testes are congenitally absent the prostate is likewise not developed.

While these observations show that there is a close relation between the development of the prostate and that of the testis, it can not be maintained that they have a direct bearing upon the question as to the effect of castration upon the prostate in adults, and it is not fair to assume that because there is atrophy as the result of developmental defects, atrophy will also occur in an hypertrophied prostate by removal of the normal testicle.

Launois has further called attention to certain interesting facts bearing on the effect of castration upon the normal prostate. His own experiments correspond with those conducted by Dr. White and Dr. Kirby, that the prostate invariably shrinks as the result of castration in animals. He examined the genital organs in bulls, sheep, and horses, and found that in all cases there was marked atrophy of the prostate after castration. In a number of dissections in bulls and oxen he always found the same result—namely, that the prostate in the castrated animal was small and hard, and that the vesicule seminale were reduced to about a quarter of their normal volume.

Observations which show the result of castration upon the prostate in man are not numerous, but those cases which have been examined all go to show that after the removal of the testicles the prostate sooner or later undergoes shrinkage. Godard, in his celebrated memoir, gives us the result of a post-mortem examination made upon a eunuch, and shows that the prostate was completely atrophied and of about the size of that of an infant. Gruber, quoted by White, has observed a very marked atrophy of the prostate in a man sixty-five years of age, who had been castrated when a youth. Bilharz has, according to Launois, confirmed these observations by the examination of two Ethiopian eunuchs. Launois himself gives an account of a eunuch examined in Paris in December, 1893, who had been deprived of his external genitals at the age of eleven. At this time the patient was fifty-six years of age. A rectal examination in this case failed to detect any trace of the prostate.

I have been able to confirm these facts in a measure, and desire to call attention to the following cases, which are in point:

Case I.—M., thirty-five years of age; left testicle removed on account of advanced tubercular disease in 1889, at Bellevue Hospital. Right testicle removed at patient’s urgent request in 1894, for neuralgia. An examination made in November, 1893, showed the prostate to be very small. The apex consisted of a hard ring; the lateral lobes seemed to be about equal in size and very much smaller than normal.

Case II.—Patient admitted to Bellevue Hospital in December, 1894, with perineal fistula. The right testis had been removed two years previously during an operation for the radical cure of hernia. The right side of the prostate was distinctly smaller than the left.

We may now turn to consider the cases in which castration has been performed for the relief of enlarged prostate.

Case I.—Reported by Rann. Prostatic hypertrophy in a man seventy-three years of age. Dysuria for fifteen years. Prostate of about the size of an apple. The patient had not been catheterized for two years. Urinates every hour; does not empty his bladder; the prostate could only be overridden by a catheter when two fingers were introduced into the rectum. The patient had an advanced chronic cystitis; the urine was foul and contained blood. Operation, April 25, 1893; double castration. Three days after the operation the size of the prostate was appreciably diminished, and this diminution continued. At the end of some months the patient passed water twice at night and three or four times during the day.

Case II.—Reported by Rann. Prostatic hypertrophy in a man in his sixty-eighth year. In 1877 the patient was treated for urinary retention. Since 1887 he has used a Nélaton catheter, sometimes introducing it two or three times an hour. In 1892 suprapubic puncture was made to relieve retention. On his admission to the hospital the patient’s bladder was distended nearly to the umbilicus, and the catheter was passed with great difficulty. Operation, April 25, 1894. The night after the operation the patient passed eighty cubic centimetres of urine in a jet. The prostate diminished rapidly in volume. On May 6th there was marked diminution in its size. The following week the patient passed water seventeen times in twenty-four hours. Two months after the operation he was obliged to urinate four or five times daily and once at night. The prostate feels soft.

Case III, IV, and V.—The three cases of Dr. F. L. Hayes, who was the first to perform this operation in America, are of no scientific value, owing to the very imperfect reports which he gives. The fact that he operated in three cases is about all the information which he has seen fit to give. In his letter published in the Buffalo Medical and Surgical Journal the following facts appear:

1. Double castration in a case of prostatic hypertrophy where the symptoms had lasted two years. He announces that eighty-four days after the operation “the patient is actually cured.”

2. This he described as a desperate case, complicated by acute cystitis and the morphine habit. The catheter was inserted every two hours. Operation, double castration. He states that the cystitis disappeared after the operation and the patient passed urine spontaneously. At the time of writing he used the catheter every four or five hours. He also states that in this case the morphine habit was cured, and the patient’s general condition at the time of writing was good.
3. This patient was operated on fourteen days prior to the time it was reported. He states that catheterism was almost impossible, owing to the abnormal development of the prostate.

The result in this case was not stated.

Case VI.—By Dr. Fremont Smith. This was fully reported to the Genito-urinary Section of the New York Academy of Medicine last spring. The patient was an old man with prostatic hypertrophy and cystitis, general infection, and threatened uremia. Double catheterism was performed; the catheter was used twice daily at first. Twelve weeks later the patient reported to Dr. Smith that he had gained forty-five pounds in weight, and had no symptoms of cystitis.

Case VII.—Reported by Dr. J. W. White. Hypertrophy of the prostate in a patient sixty-nine years of age; prostate very large, of the size of a small orange. The patient had not passed water except by catheter for some years. Urine very foul and ammoniacal, loaded with pus, and sometimes containing blood. Operation, double catheterism, performed January 31, 1894. Fourteen weeks later the patient could pass water through the urethra. Rectal examination showed a great diminution in the size of the prostate, which was nearly normal. A catheter introduced before the operation showed the length of the urethra to be twenty-six centimetres; its length at the time the report was made was only twenty centimetres. The introduction of the catheter was easy and painless.

Case VIII.—Reported by Mayer and Haenal in the Centralblatt für die Krankheiten der Harn- und Sexualorgane, August 23, 1894. Operation performed May 16, 1894, on a man about seventy years of age, with a much enlarged prostate, with cystitis and ammoniacal urine, tenesmus, and toxemia, in whom catheterism was becoming impossible on account of the pain it produced. There were several oozers of residual urine. Some improvement was noted within a few days after the operation, and in two weeks the tonicity of the bladder began to return. In three weeks the urine was nearly normal. In six weeks the prostate had shrunk to its proper dimensions, and the bladder emptied itself completely, no catheter being required. Urination was performed only once every four hours; the urine was acid in reaction.

Case IX.—Moulin, in the Medical Press and Circular, September 19, 1894, reports the case of a man about eighty-one years of age with complete retention due to prostatic enlargement of the size of an orange, with cystitis and failure in general health, in whom catheterization was impossible, all attempts being followed by haemorrhage. Suprapubic aspiration was necessary on several occasions. After double catheterism the improvement was almost immediate. The prostate was appreciably smaller in ten days, and in three weeks it had practically disappeared. The bladder had regained power. The urine was nearly normal.

Case X.—Dr. J. J. Thomas, in the Pittsburgh Medical Review, September, 1894, reports a case in which castration in a patient, sixty-five years of age, who had had symptoms of prostatic hypertrophy for fifteen years, had caused “considerable improvement.” Urination, which had formerly been very frequent, was now necessary but three times daily. No further details are given.

Case XI.—Dr. B. M. Ricketts, in the Cincinnati Lancet-Clinic, December 1, 1894, reports a case in which he performed this operation in a patient about seventy-four years of age who left the hospital at the end of the sixth day. On the second day after the operation the patient could urinate with greater ease, and the pain was slight. He could sleep four hours at a time during the night, whereas formerly he had been obliged to urinate every hour, and had been urinating thirty times daily. His condition had continued to improve.

In studying these cases there are several points which at once attract attention. In the cases reported we have very little information given as to the pathological conditions present in the prostate. The size of the prostate, as ascertained by rectal examination, is sometimes given, and in White’s case the length of the urethra. The existence of a cystitis is noted in most cases, but we can form very little idea from the reports as to the degree of cystitis, or as to the portion of the prostate enlarged; as to the condition of the vesical muscle, or as to the degree of vesical atony or hypertrophy present. Without these facts it is impossible to estimate the value of the results obtained. In cases of advanced hypertrophy of the prostate there are other factors to be considered as to the method of treatment to be adopted besides the mechanical obstruction. While I do not believe that there are sclerotic changes in the vessels of the bladder in all cases of prostatic hypertrophy, as maintained by Guyon, there certainly are in some; and in these, atrophic changes in the prostate produced by castration would not cure the diseased condition of the vesical walls.

Secondly, in all cases of vesical atony, removal of the prostate or its atrophy would not restore the tonicity of the vesical muscle, and in such cases it would still be necessary to continue the use of the catheter after the operation, in order to prevent cystitis.

Another point which strikes us in the cases reported above is the very rapid diminution which occurred in the size of the prostate after the operation, and which seems to have been regarded by the various observers as the result of prostatic atrophy. Marked diminution in the size of the prostate is not an unusual feature in cases of prostatic hypertrophy associated with retention, after the retention has been relieved and its recurrence prevented by careful and skillful use of the catheter. I have met with many cases of prostatic hypertrophy and retention where rest in bed, fluid diet, and careful aseptic use of the catheter so reduced the prostatic edema as to result within a few days in very easy catheterism, and in many instances in voluntary micturition.

I am ready to admit, for the sake of argument, that double castration may cause a shrinkage in the prostate, but I cannot believe that the atrophy will be so marked as to be clearly appreciated within a few days or weeks after the operation, in spite of Dr. White’s experiments on dogs and the results obtained in the cases thus far reported. Atrophy of the prostate after castration, if it occurs, must be the result of trophic changes, and it does not seem possible that the shrinkage would be so rapid as is alleged. The diminution in the size of the prostate induced in these cases, and the voluntary evacuation of the bladder are, I believe, more likely to be the result of rest in bed and careful catheterism than of atrophy.

I do not care to speak here of the repugnance to this operation which many patients would naturally feel even at a period of life when the sexual question is not an important factor. There is great danger, I fear, however, that the operation will be performed too often and without due deliberation, owing to the enthusiastic way in which those who have performed it have urged its merits. I am
convinced that equally good results are to be obtained by
dilatation of the prostatic urethra and perineal drainage as
from castration; and in the majority of cases of advanced
prostatic hypertrophy requiring operation, I should prefer
the more certain method of treatment by prostatectomy to
this uncertain though much easier operation.

Castration in prostatic hypertrophy can at present be
offered to a patient only as a physiological experiment;
and while I do not object to scientific experiments, I be-
lieve that they should be conducted in a scientific manner,
and that the reports of these experiments should be given
in detail. I hope that those who report cases in the future
will give more fully and in greater detail the history and
condition of each case both before and after the operation,
and in addition, that they will give careful note of (1) the
“catheter history” of the patient; (2) the effect of rest
and regular catheterism prior to the operation; (3) the
portion of the prostate enlarged; (4) the condition of the
vesical muscle; (5) the amount of residual urine; and (6)
the length of the urethra, taken at various times.

5 West Fifty-eighth Street.

INOCULATION INTO ANIMALS
AS THE ONLY DECISIVE METHOD
FOR THE BIOLOGICAL DIAGNOSIS OF TRUE DIPHTHERIA.
ILLUSTRATED BY THREE CASES*

By EDWARD C. RUNGE, M.D.
INSTRUCTOR IN PHYSIOLOGY AND ASSISTANT CLINICIAN TO
THE CLINIC FOR SERIOUS DISEASES OF THE ST. LOUIS MEDICAL COLLEGE,
MEDICAL DEPARTMENT OF WASHINGTON UNIVERSITY, ST. LOUIS.

Before submitting the suggestion implied in the title of
this paper, I shall first place in evidence the cases that were
in reality the starting point for the present communication:

On January 28th I was called to see Hannah S., aged six
years, who, according to her mother’s statement, had com-
plained of chilliness a few days before, of pains in the side and
front of chest, of severe headache, and a painful stiff neck. She
was said to have had some fever, severe coughing spells, com-
plete anorexia and constipation, but no vomiting. The family
resides in my immediate neighborhood, hence I was in the posi-
tion to know that no severe infectious diseases, except some
cases of measles, were to be found near the residence. The
last case of diphtheria, near by, had occurred three years ago,
and remained the only one on record. There is a well on the
premises, but its water is used exclusively for manufacturing
purposes, the family supply being furnished by the city water
works. The house is new, had no previous occupants, and does
not show any sanitary defects.

My examination of the little patient elicited the following:
As to subjective symptoms, there were severe pains in the neck,
in left side of chest, and behind the sternum, very much aggra-
vated by the cough, which was dry, irritating, almost continuous;
she also complained of headache and aches in her limbs. Axillary temperature, 102° F.; pulse rapid, the exact rate not
having been recorded. No delirium or stupor. No rhinitis. The
inspection of the throat revealed a simple angina, with swollen
tonsils and general hypertrophy; none of the tonsillar crypts
appeared plugged. There was some lymphadenitis on both sides.
The voice was clear. Some broncho-pneumonic patches were
made out on the left side. Having satisfied myself that I was
confronted with a case of streptococceous angina, I satisfied the
parents by rendering a provisional diagnosis of *grippe*. The
other three children appeared to be perfectly sound. On the
next day the picture presented by the patient was much the
same, except that the cough seemed to be harsher, more ring-
ing, accompanied by a peculiar rattling sound in the trachea.
A suspicion of having possibly to deal with a case of pseudo-
menabraneous croup flashed upon me. I at once examined the
other children, and found in the two next elder ones a simple
hyperemic condition of the throat, with tonsils slightly swollen
and some lymphadenitis. The baby, four months old, appeared
normal. On that day I made swab cultures of the three throats.
The report received from the health department on January
30th, and the same, in more amplified form, on February 11th,
read as follows:

No. 120, Hannah S., not diphtheria. Staphylococcei and
streptococcei in great numbers.

No. 123, Louisa S., true diphtheria. Bacillus diphtheriae
with great numbers of staphylococcei and streptococcei.

No. 125, Rudolph S., the same as No. 123.

To say that I was amazed would hardly express my feelings
at the receipt of this report. I proceeded without delay to
have the house placarded and to isolate the youngest child, which I need not mention any further, as it escaped unharmed.

On January 31st, Hannah showed signs of improvement, her
temperature ranging from 101° in the morning to 100° at 10.30
p. m.; pulse, 106 to 120. Louisa, aged five years, was appar-
ently well. Rudolph, aged three years, seemed to be somewhat
out of sorts in the morning about nine, but nothing unusual was
noticeable. At 2 p. m. I found him on his bed, delirious, toss-
ing about wildly, picking at the bedclothes, the very picture of
some acute toxemia. Axillary temperature, 103° F.; pulse, 130.
The throat was simply congested, the lymphadenitis more
pronounced on both sides, the cough dry and harassing, without
expectoration. A few broncho-pneumonic patches were made
out. On the eve of February 1st, Louisa was taken with severe
vomiting after too hearty a supper. Her temperature was not
over 102° (the record in her case could not be found). She
complained of the same pain in the sternal region of the chest
as her elder sister, but no pulmonary lesion was discoverable.
The throat had exactly the same appearance as in the other
two cases. The lymphadenitis was very slight.

The subsequent course in the three cases was the fol-
lowing:

Hannah’s temperature registered normal on February 1st
except that 99.4° was recorded by the nurse about midday.
This record was kept up until February 10th, showing but
slight variations from normal; if anything, there seemed to be
a tendency to subnormal—i.e., 98°. The pulse rate diminished
gradually from 118 to 76. The lung cleared up, the throat
symptoms disappeared, and the child was left not any the worse
for the attack, except for a slight degree of anemia.

Louisa was sick but two days; her temperature returned to
normal in that short time, and all the other symptoms cleared
up completely.

Rudolph’s case proved far more refractory. His temper-
ature was irregular, but constantly above normal through the
total twenty-four hours; it ranged between 99° and 100°
in the morning, to 102° and 103° in the evening. On February
10th, 98.2° was registered, and after that the temperature re-
mained normal. The pulse varied between 130 and a rate
which defied any attempt at actual count, but I have counted,
on several occasions, as many as 160 beats. On February 2d my attention was called to a discharge from the boy's left ear. I washed it out with water and peroxide of hydrogen, cleared it out with a Politzer's bag, but succeeded in getting only some fresh blood; no purulent material made its appearance at any time. After a few days of treatment the discharge subsided. An aural examination on March 10th revealed some cerumen, which was removed. A further examination was rendered very difficult by the high degree of belligerency displayed by the little fellow. Still, I thought I could discover a perforation in the superior posterior portion of the tympanic membrane. The mother then stated that the patient had had a discharge from one of his ears about a year ago.

From the day of the disappearance of the fever, all three patients made a rapid and complete recovery. No albuminuria or paralysis has ever occurred.

The reports of the health department on the swab cultures made after the one spoken of above, were the following:

The experimental work bearing upon the bacteriological features of the reported cases was done by Dr. William N. Beggs, pathologist to the St. Louis Medical College, to whom I express my thanks. The methods and results were the following:

The impure blood-serum culture was plated out, and from the plate a number of pure cultures were made in glycerin-agar, in agar, in bouillon, and on potato. The first three showed the characteristic growths of the Klebs-Loeffier bacillus, its morphology having been established by numerous cover-glass preparations. The cultures on potato were invisible, but demonstrable by the microscope. On March 15th, a rabbit was tracheotomized, and the tracheal mucous membrane scarified; some of the pure culture was rubbed into the denuded surface. On March 18th a guinea-pig received subcutaneous inoculations with two different cultures at two different places of its abdomen. The animals are alive, and never presented a sign of general disturbance. The tracheotomy wound of the rabbit healed kindly, and the guinea-pig showed just a very slight elevation at the places of inoculation, not any more than could be accounted for by the operative procedure. For lack of time no attempt was made at observation of the cultural behavior of the bacillus.

These three cases, while differing in intensity, give plain clinical evidence of a similar pathogenesis. In the anticulture days they might have passed as streptococceous angina and toxaemia, or possibly as infections by that still somewhat enigmatical entity, the Bacillus influenza. The ringing cough and the rattling in the trachea of the oldest child, which were the starting point of further investigation leading up to this communication, would have been taken notice of, anxiously watched, and their partial disappearance on the very next day hailed with satisfaction. As the Klebs-Loeffier bacillus has been demonstrated by Martin in sixty-seven per cent., and by Park in eighty per cent. of the cases of pseudo-membranous croup examined, my fears were not groundless. Still, impressed as I was with the importance of the recently introduced diagnostic method I, no doubt, fell a victim to suspicion much more readily. The report of the health department on the first swab cultures proved, or seemed to prove, my apprehension causeless with regard to the suspected case, while pointing to imminent danger in quite unexpected quarters. You can see at a glance that the clinical picture in the cases reported was diametrically opposed to the result of the bacteriological examination. True diphtheria, the diphtheria of Bretonneau, without a trace of a fibrinous exudate, without even a plugged follicle, is unknown. Accepting this, we must account for the presence of the Klebs-Loeffler bacillus, the bacillus of true diphtheria. I should go far beyond the scope of this paper if I entered upon the consideration of the controversy as to the pathogenesis of this disease. The work of the physician and the sanitarian is pre-eminently practical. They must face conditions, not theories, hence a certain amount of dogmatism must necessarily form the basis of their labors. They are the beneficiaries of the workers on the arena of scientific research, and whatever the majority of these workers put forth as an ascertained principle or truth must prevail. Since Klebs described and Loefler announced his success in isolating the bacillus that bears their joined names the literature on this subject has assumed enormous proportions. No matter what our individual predilection may be, we can not deny that the incongruous mass of conflicting evidence will not permit us to take a bold, unassailable stand with regard to the true pathogenesis of Bretonneau's diphtheria. The Klebs-Loeffler bacillus had to run just recently the gantlet of severe though dispassionate criticism; the result of the battle can not possibly be foreseen as yet. The majority of scientists, however, still hold to the opinion that this organism is the essential diphtheria-producing agent; consequently there is nothing left to us but to acquiesce in their dictum, and to shape our course accordingly. Once having agreed upon the causal relation between the bacillus and the disease, we must direct our efforts not only upon an attempt at saving the lives of the afflicted, but also at checking the dissemination of the disease, obscure as the mode of this dissemination may appear in the light of our present knowledge and past experience. To achieve the latter end we must make in every case an impregnable diagnosis. In fully developed cases showing clearly the entire complex of symptoms of the disease, the practical clinician will have no difficulty in arriving at a diagnosis in a purely clinical way. But during the earlier phases of the disease, and in cases of doubtful nature, the bacteriological findings not only complete the clinical picture but antedate its full development. An easy method of assisting the practitioner in arriving at an early diagnosis has been devised by the Board of Health of New York city, and the same has been introduced since in our own city. This method is based upon the demonstration of the specific bacillus, principally by its morphological, less by its biological peculiarities. Let us assume that every known biological test, except inoculation into animals, was applied, and a bacillus demonstrated identical
with the Klebs-Loeffler bacillus, or nearly so, both morphologically and biologically, does this render the diagnosis of true diphtheria incontrovertible? I think not, for the literature is teeming with evidence that a micro-organism exists whose morphology and biology stamp it a genuine alter ego of the Bacillus diphtheriae, except as to virulence. Here are some of the data:

Loeffler, in his second communication on diphtheria, reported his success in demonstrating the Klebs bacillus in ten cases of diphtheria, and in isolating from the same series of cases a non-pathogenic bacillus resembling the former very closely. He also found the same micro-organism in the throat of a healthy child. He held this to be a bacillus sui generis, and called it the "pseudo-diphtheritic" bacillus. The same organism has been demonstrated by von Hoffmann and Wellenhof in 26 oral cavities out of 45 cases examined, in 1 case of diphtheria, 3 cases of measles, 6 of scarlet fever, and in 3 healthy individuals; by Babes, in cases of trachoma; by Weisser, in ulcers; by Zarnikow, on the surface of various mucous membranes; by Abbott, in 4 out of 53 patients suffering with a variety of simple, non-diphtheritic troubles; by Koplik, in 4 cases of catarrhal angina; by Beck, in 16 cases of diphtheria out of 51 examined; by Escherich, in 11 cases of non-diphtheritic affections; by Roux and Yersin, in 15 out of 45 cases of children in the Paris hospitals; in 26 out of 50 cases of healthy children in a village school at the sea shore; in 2 out of 6 cases of simple anginas; in 5 out of 7 cases of measles; by Park, in 27 out of 330 cases of healthy persons.

This is, I think, a sufficiently strong array of data to allay all doubt as to the existence of a micro-organism that crosses our path in a most surprising manner clothed in the guise of the Klebs-Loeffler bacillus. Efforts have been made in the direction of differentiation between the two, morphologically as well as biologically, principally by Loeffler, von Hoffmann, Roux and Yersin, Martin, Zarnikow, Escherich. In the following I have attempted to condense the results of these efforts in a tabulated form:

I. As to morphology, the pseudo-diphtheritic bacillus is said to be:
1. Shorter and thicker.
2. More frequently club-shaped at the extremities.

II. As to biology:
1. Its colonies on blood serum are but few—from one to four.
2. Its cultures in bouillon and agar are more abundant.
3. It grows less abundantly in a vacuum.
4. Its cultures continue to grow at a temperature of 20° and 22° C., at which the true bacillus grows very slowly.
5. Its isolated colonies show more distinctly indentations in their outline.
6. The colonies on blood serum, agar, and gelatin are whiter, and those on blood serum appear more moist.
7. The pseudo-diphtheritic bacilli are seen to be arranged in their colonies either parallel to each other or converging to one point, like the spikes of a wheel, while the Klebs-Loeffler are found in irregular heaps, or lying crosswise.

8. Frequently a peculiar pigmentation is produced in old agar stab cultures of the pseudo-diphtheritic bacillus, the agar turning brown to brownish black from above downward, similar to a well-smoked meerschaum holder.
9. Its cultures in bouillon become acid and then alkaline, just as those of the true bacillus; but the change occurs much sooner.
10. The pseudo-diphtheritic bacillus is absolutely non-virulent to the animal that is so exquisitely susceptible to the diphtheria virus, the guinea-pig.

If we exclude the point pertaining to the atoxic nature of the pseudo-diphtheritic bacillus, we must admit that all the points of differentiation are based on comparative tests, the decision in every instance being left entirely to the subjective impression of the individual observer. No allowance for error of judgment or unintentional bias is made. In speaking of the differential points brought out by Loeffler and von Hoffmann, Baumgarten (1) characterizes them as "graduell und z. Th. ziemlich differier Natur," and questions the constancy of their occurrence. According to him it would have been rather surprising if the different behavior of the two organisms on agar should have escaped Loeffler's attention. He also mentions that Fluegge, in direct opposition to von Hoffmann, designates agar as an exquisite culture medium for the Klebs-Loeffler bacillus. I call your attention to the result of Zarnikow's experimental work, as quoted by Escherich (2). He found that no acid is formed in bouillon cultures of the pseudo-diphtheritic bacillus, which is contrary to the results of Roux and Yersin and Escherich. Here is presented to us a rich field for valuable corroborative work, in some of which Dr. Beggs and myself intend to engage in the near future, availing ourselves of the biological material in our possession.

If the first nine points of differentiation are unsatisfactory and nearly useless, the tenth is reliable and conclusive, for the non-virulence of the pseudo-diphtheritic bacillus has been demonstrated without a single dissenting voice. It does not matter in the least whether we consider, with Loeffler, Escherich, Zarnikow, Bernheim, and Morel, this bacillus an organism sui generis, or with von Hoffmann, Roux, Martin, and Fraenkel a non-virulent variety of the bacillus of true diphtheria, as long as no experimental evidence is adduced as to the possibility of the former actually regaining its supposedly lost virulence. Roux has succeeded in experimentally decreasing and increasing the virulence of the Klebs-Loeffler bacillus, but his attempts at rendering Loeffler's pseudo-diphtheritic bacillus virulent have so far met with complete failure. His assumption that the latter may under favorable conditions regain its virulence is purely speculative, and experimentally without proof. When Fraenkel draws his conclusions from analogies with the pneumococcus, he falls very far short of settling the disputed point, especially considering the extremely imperfect knowledge that we possess with regard to the true biology of the individual micro-organisms. Baumgarten has a strong leaning toward Roux's views. As the words of a man of his scientific accuracy must naturally carry great weight with us, I shall quote a passage from
his Lehrbuch der pathologischen Mykologie (1890), pp. 701 and 702:

“Apart from all analogies we are of the opinion that von Hofmann has adduced strong evidence as to the identity [of the two organisms] in establishing the fact that the diphtheritic bacillus is capable of relinquishing spontaneously and completely its most characteristic property—i.e., its infectiousness. This being the case, we are justified in assuming the possibility of the same bacillus changing spontaneously from a state of non-virulence to one of virulence. We were obliged to pronounce the small morphological and cultural differences between the pseudo-diphtheritic and diphtheritic bacilli as insufficient proofs of their belonging to a different species, but just these differences agree very well with the assumption of a simple change from a virulent (parasitic) to a non-virulent (saprophytic) state of existence.” Thus Baumgarten. This is interesting from a speculative point of view; still, it is theoretical deduction without experimental evidence. As directly bearing upon the vital portion of this paper, I can not very well omit to quote from an article by Dr. Flexner, of Johns Hopkins University (3):

“Among the most important results of the bacteriological study of the inflammations of the throat and air-passages has been the discovery that cases which present the features of a mild catarrhal angina or a lacunar tonsillitis may be associated with the presence of the Bacillus diphtheriae, and that from these can arise other cases in which membrane is found on the fauces. This class of cases has been studied by Escherich and Feer, and especially by Koplik. Within the past few weeks I have seen two such instances in the practice of Dr. W. D. Booker, and from them obtained the Loeffler bacilli in cultures.” The two cases spoken of by Dr. Flexner were: one of a girl with lacunar tonsillitis; the plugs from the tonsillar crypts contained the Loeffler bacillus. The patient recovered rapidly. The other was that of a child with very much swollen tonsils, but no visible membrane; cultures from the throat showed the presence of the Bacillus diphtheriae. Dr. Flexner has utterly failed to prove by his cases that from them ever arose cases in which membrane was found on the fauces, and as he confined himself in making his bacteriological diagnosis to cultures, he has not given any proof as to the true nature of the bacilli obtained.

From the evidence cited we may deduce two propositions:

1. The existence of an absolutely non-pathogenic, hence saprophytic, alter ego of the Klebs-Loeffler bacillus must be accepted beyond doubt.
2. Under no conditions, artificial or natural, has this bacillus been proved to acquire virulence.

Acting upon these propositions, the sanitary man must differentiate in every single instance confronting him between the Klebs-Loeffler and the pseudo-diphtheritic bacillus. He is not engaged in fighting saprophytes; he is even powerless in dealing with the most virulent bacilli if the latter are demonstrated on the mucous surfaces of healthy individuals, which has been done repeatedly. The absolute, I may say the only, method to arrive at a diagnosis is found in establishing the virulence or non-virulence of the microorganisms obtained by culture, and recognized morphologically; consequently this is the only method for the practical sanitary.

My suggestion as to the mode of procedure is as follows:

Sterilize glass tubes of small caliber containing cotton swabs. Place these in tightly fitting wooden cylinders, and the whole in strong envelopes bearing the address of the health department, and each containing a case slip.

Place the tubes at distributing depots of easy access, and direct the physician, after having applied the swab in the usual way and filled out the case slip, to return the tubes by mail.

Make a diagnosis in the manner now practiced. If the microscope reveals the presence of an organism morphologically identical with the Klebs-Loeffler bacilli, advise the attending physician of this fact, and also of the coexistence of other important micro-organisms. He will have the premises placarded as diphtheria, and will see to the patient’s isolation.

Proceed at once to inoculate into a susceptible animal, preferably a guinea-pig, a quantity of a pure culture. Upon the appearance of a local exudate, considerable infiltration or edema, or of necrosis, record the case as one of true diphtheria; advise the physician of the result, who will continue the isolation of the patient until the swab cultures give a negative result. Then treat the premises according to prevailing sanitary methods.

In case the animal should not show any sign of a local lesion or general disturbance, remove the placcard and all sanitary restrictions, and do not place the case on record at all, or record it as anything but true diphtheria.

I will say a few words with regard to some of the technical features of this plan:

The use of the mail as a medium of transmission of the swab tubes is perfectly feasible. It has been tried successfully in Germany, as reported by Dr. Hesse (4). It would save the physician a great deal of time and inconvenience.

In advocating the omission of the blood-serum tubes I follow Dr. Hesse’s suggestion. The serum would not be vitiated by drying or in any other way. The slant cultures would be made uniformly by a trained specialist. It may be mentioned that Dr. Hesse succeeded in obtaining abundant cultures of the Klebs-Loeffler bacillus from dried swabs eight days old.

The information as to coexisting micro-organisms, especially streptococci and staphylococci, is of great importance to the attending physician in the light of our growing knowledge on mixed infections.

To await the death of the inoculated animal before taking the necessary sanitary steps is unessential from a practical standpoint. The appearance of a local lesion of any severity is an all-sufficient criterion in establishing the virulence of the bacillus obtained. In this connection I mention Bernheim’s (5) exceedingly instructive work on Mixed Infections in Diphtheria. He reports the following results from inoculation into seven guinea-pigs of rather large doses of pure cultures of the pseudo-diphtheritic bacillus, together with filtrates from cultures of the Strepto-
coccus brevis and conglomeratus: In five, no change whatever occurred; in one appeared a trace of an infiltration; and in one, a very slight infiltration.

As the office of the city bacteriologist was created essentially for sanitary and not scientific considerations, the swab cultures made for the purpose of determining the final disappearance of the Klebs-Loeffer bacillus should not be made oftener than once, or at the most twice, a week. It has been ascertained that the bacillus in the great majority of cases disappears in from two to three weeks after the subsidence of the local diphtheritic process.

Now, let me consider a few objections that might be raised against the proposed plan of operation. The increased cost should hardly enter into consideration.

The danger of a dearth of animals necessary for the experimental work is very remote, for there never yet was a demand created but that the supply kept pace with it. Besides, it may prove practicable and more saving for the health department to organize an animal farm on a large scale. The objection to the early removal of the placard will not hold, as the physician, by exercising tact and discretion, will always succeed in covering his retreat with proper decorum. People, as we all know, are only too anxious to forego the distinction of living in what practically amounts to a pesthouse.

In conclusion, I will enumerate a few points that seem to me to render the adoption of inoculation into animals in every case of suspected diphtheria imperative:

1. We should be enabled to remove the ban from premises that are as groundlessly stigmatized as those would be on which any other disease of infectious, possibly contagious, but benign nature occurs. There is certainly no occasion for placarding a house containing a case of follicular amygdatitis or streptococcous angina, whether in the absence or in the presence of the pseudo-diphtheritic bacillus, the latter having been proved to be but a harmless saprophytic admixture. An attempt to proceed to such extremes would raise an uproar in the community that few of us would have the hardihood to face. Successful sanitation is largely based upon the sympathetic support of the community at large; hence the burden should be made as light as possible within the limits of public safety.

2. The patients not having yielded the pathogenic bacillus would be enabled to benefit at a much earlier period from those most powerfully reconstructive therapeutic agents, compared with which all the drugs of the pharmacopoeia sink into insignificance—fresh air and outdoor exercise. They would not be needlessly proscribed as threatening foci of infection for many weary weeks.

3. A whole measure is ever preferable to a half measure; the former would prove of valuable assistance to the practicing physician, while the latter would more frequently create doubt and confusion.

4. Our statistics would not run the danger of unintentionally misrepresenting the actual state of affairs. This I consider the pièce de résistance in my argumentation, for statistics—and with these I mean the genuine, unvarnished article—are our mainstay in getting at truly scientific deductions.

HYPNOTISM AND CRIME.

A REPLY TO DR. WILLIAM LEE HOWARD.

BY THOMSON JAY HUDSON, WASHINGTON, D. C.

It often transpires in the course of a controversial argument between two individuals that what seems to be an irreconcilable difference of opinion is really nothing more than the result of a misunderstanding by one, or by each, of the other's terminology. A striking example of this is developed in the reply of Dr. Howard in my paper published in the Journal of January 26th, entitled Hypnotism in its Relations to Criminal Jurisprudence. A hasty reading of Dr. Howard's very interesting article would naturally lead one to suppose that he entertained views decidedly adverse to mine. Indeed, it is quite evident that he thinks so himself. I believe, however, that I shall be able to convince him that we are in entire accord, and that our seeming disagreement arises wholly from his misunderstanding of my terminology.

The first and most important misapprehension of his relates to the term laboratory experiments, which I used rather freely and without explanation or qualification other than that afforded by the context. It is a term commonly employed in works on hypnotism, and I do not find any warrant in any of them for the restricted definition which Dr. Howard evidently attaches to it. He says:

"I fully agree with Mr. Hudson as to the inefficiency, from a medico-legal view, of the value of 'laboratory experiments,' so I shall not refer to them."

I infer from this remark, taken in connection with what follows it, that he limits his definition of the term laboratory experiments to those experiments which are actually made in the laboratory, for he follows his disclaimer by the citation of a number of cases, each of which comes clearly within the term as I employed it, clearly within the principles which I sought to enforce, and obviously, it seems to me, within the definition which I inferentially gave. If Dr. Howard will carefully reread my article he will find that I laid particular stress upon "suggestions of the environment," which consist of "those suggestions which arise spontaneously in the mind of the subject from his knowledge of the nature of the experiments about to be made, of the character of the persons present, the objects of the experiments, and the desires of the experimenters." Dr. Howard freely acknowledges the potency of the most important of these suggestions in "laboratory experiments" in the following words:

"I fully agree with Mr. Hudson as to the inefficiency, from a medico-legal view, of the value of 'laboratory experiments,' so I shall not refer to them."
"It is undoubtedly true that in those experiments the subjects know that they are surrounded by friends and presumably honest men, and that no harm can come to them; so they carry out all the farcical suggestions."

It will thus be seen that Dr. Howard does not antagonize my position concerning the potency of the suggestion embraced in the knowledge which the subject possesses of the character of those present, including, of course, that of the hypnotist. It goes without saying that this knowledge, with the consequent suggestion, enters as a factor into all experimental hypnotism, whether the experiments are made in a "laboratory," or in a private parlor, or in a public restaurant, or on the street. It will be seen, therefore, that the term laboratory experiments is entitled to a much broader definition than Dr. Howard seems to attach to it. Indeed, it is practically impossible to eliminate that form of suggestion in any experimental case whatever. Certainly Dr. Howard has not mentioned any experiment where that factor was absent. It follows that his cases have no possible evidential value. Indeed, they serve to emphasize what I had to say regarding the potency of suggestions of the environment in experimental hypnotism, and Dr. Howard will be the first to acknowledge that in neither case mentioned was there a possibility of criminal intent, either on the part of the hypnotist or of the witnesses. On the contrary, he does not mention a case where the suggestions of the environment were not such as to preclude all possible suspicion that there would be the slightest danger in carrying out "all the farcical suggestions."

Again, Dr. Howard takes issue with my remark that "no one can be hypnotized against his will"; and again the supposed difference seems to arise from a difference in our understanding or employment of terms. I took pains to define the term will, as I employed it, for the express purpose of avoiding any misunderstanding; but Dr. Howard seems to have overlooked my definition. The following is the language employed: "Will, in the psychic sense, is nothing more nor less than desire." This definition is strongly insisted upon by Schopenhauer, and it finds warrant in every standard lexicon with which I am acquainted. I restricted it to the "psychic sense" for the reason that it is emphatically the only definition that will cover all the facts in psychic science. In this sense the truth of my proposition is self-evident, that "if the subject's desire to obey the dictates of conscience is stronger than his desire to obey the suggestions of the hypnotist, the auto-suggestion must prevail." And this proposition covers the whole question of "hypnotism and crime." It is equally self-evident that, under this definition of will, if the desire of the subject to resist the suggestion of the hypnotist is stronger than his desire to be hypnotized, he will resist. Dr. Howard will not deny the truth of this proposition when it is restricted to experimental hypnotism. It is true that he undertakes to cite a case where "the only suggestion is a self-suggestion, such as a determination not to be hypnotized"; but he illustrates with an experimental case where he hypnotized an acquaintance in the presence of another acquaintance, the two being friends of each other. Dr. Howard certainly does not seriously hold that such a case is illustrative of his proposition. On the contrary, it must be as evident to him as it is to others that every factor was present in that experiment that conspires to render the ordinary "laboratory experiment" invalid. To say the least, there was nothing in the experiment that could have any possible bearing upon the question of "hypnotism and crime." We must, therefore, relegate that case to the category of those "laboratory experiments" which Dr. Howard agrees with me in declaring destitute of evidential value.

Again, Dr. Howard seems to take issue with my statements illustrative of what I have termed a volitional auto-suggestion. The paragraph alluded to reads as follows:

"A volitional auto-suggestion is one which the subject makes to himself before being hypnotized. For instance, if he anticipates the possibility that the hypnotist will place him in a ridiculous attitude, or one repugnant to his sense of propriety, he will resolve beforehand that he will not obey the suggestion. If, then, the anticipated suggestion is made by the hypnotist, it will be strongly resisted, and the potency of the resistance will be in exact proportion to the subject's innate sense of dignity or propriety. If that is very strong, and the hypnotist insists upon his suggestion, the subject will be restored to his normal condition."

To this paragraph Dr. Howard makes the following reply:

"I have caused B. B., mentioned before, to defecate in his trousers. Please do not look upon this from a vulgar point of view, for, after several years' observation of 'laboratory experiments' in Europe, I determined to get away from this unsatisfactory method of arriving at conclusions. If, as Mr. Hudson states, the subjects will do nothing distasteful to them, as an investigator I was in duty bound to settle the question."

With all due deference to Dr. Howard's superior facilities for observation in Europe and experiment in this country, I must say that he has adopted a very singular method of getting away from the unsatisfactory "laboratory experiments" of Europe, as well as of disproving the legitimacy of my conclusions. At least he has left out of his report of B. B.'s case all that could give value to such an experiment. The only thing that he has rendered reasonably certain is that he has made a "laboratory experiment" of his own in order to "get away from the unsatisfactory" laboratory experiments of his European predecessors. It is just possible, however, that he selected an apartment more appropriate than the laboratory for such an experiment; but I submit that he did not "get away" from the principle involved. Be that as it may, he has left some very important particulars out of his report, so that it is impossible to know whether he has succeeded in disproving the soundness of my conclusions. In the first place, he has not stated whether B. B. had any reason to anticipate such an experiment. If he had no reason to anticipate such an experiment he would have no opportunity to "resolve beforehand that he would not obey the suggestion." Hence it is impossible to know whether the conditions precedent which I named were complied with.
But the fundamental error which Dr. Howard has committed consists in not discriminating between the effect of suggestion upon the normal functions of the body and its effect upon the moral conduct of the subject. It does not follow, because, in a private experiment conducted by mutual friends, the normal functions of the body may be stimulated by suggestion to unwonted activity, that the same subject could be made to perpetrate a crime or to commit an overt act of impropriety in a mixed company. And this is really the only point upon which Dr. Howard and I seem to differ seriously in opinion.

But let us not be led astray by the discussion of irrelevant collateral issues. The whole question of "hypnotism and crime" is in a nutshell, and it only requires just a little clear thinking to solve the problem. My proposition was, and still is, that whether an hypnotic subject will obey a criminal suggestion is "purely a question of moral character." The truth of this proposition will become evident when we consider the following propositions:

1. Persons in an hypnotic condition are constantly amenable to control by suggestion. This proposition no hypnotist will attempt to dispute. It is the fundamental law of hypnotism.

2. When two contrary suggestions are made to a subject the stronger suggestion necessarily prevails. This proposition is self-evident.

3. Other things being equal, an auto-suggestion is as potent as a suggestion by another. This fact is recognized by all hypnotists.

4. Moral character is a primordial anterior suggestion that neutralizes a criminal suggestion.\*

It is a corollary of these propositions that, as I remarked in the article under consideration, "if the subject's desire to obey the dictates of conscience is stronger than his desire to obey the suggestions of the hypnotist, the auto-suggestion must prevail."

No amount or quality of sophistry can weaken the force of these self-evident truths; for it is a self-evident proposition that, where two opposing forces come in conflict, the stronger force must prevail; and it is just as true of a moral force as it is of physical force.

It must not be forgotten that I distinctly held, in the article under consideration, that "a criminal hypnotist in control of a criminal subject could undoubtedly procure the commission of a crime"; but that it was "purely a question of moral character." In fact, this was the motif of my argument; and my conclusion was, and is, that "when a man sets up hypnotism as a defense in a criminal trial he proclaims himself a criminal character."

Those who believe that the suggestions of a hypnotist could have caused St. Anthony to outrage his grandmother, talk needlessly of "inhibiting" this tendency to obey the stronger suggestions of moral education and character. This is simply begging the question; for how can the tendency to obey one suggestion be "inhibited" otherwise than by a stronger counter-suggestion? A law of Nature can not be "inhibited."

Dr. Howard himself freely admits that it is true "in a general sense" that only those who "have evil and criminal instincts can be made to commit crimes under hypnosis suggestion"); but qualifies the remark by saying that "we must not forget that most of us have some latent or undeveloped animal or immoral germ hidden and inactive in our psychical organization." I submit that a criminal instinct is a criminal instinct, whether it is latent or patent, whether it is constantly active and observable, or is hidden and becomes recurredent only in the presence of temptation or suggestion.

It will thus be seen that Dr. Howard's idea that he differs with me on the main question is erroneous. I have already shown that we are in accord in declaring laboratory experiments to be valueless as evidence on the question of hypnotism and crime; although, in attempting to disprove the correctness of my conclusions, he has cited nothing but laboratory experiments. I realize the fact that he had no others to cite, for he tells us that he has carried his "investigations to the utmost limits, stopping only at suicide, murder, and seduction, feeling that the subject is so full of great social actuality that we are bound to face it." It is obvious therefore, that before he can settle the question definitely he must enlarge his field of observation.

In conclusion I desire to say that, having shown clearly that Dr. Howard is in perfect accord with me on all the important questions involved, I shall indulge the hope that he will join me in deprecating the proposed legislation which is based on the assumption that hypnotism, outside of the medical profession, must necessarily be employed for the perpetration of high crimes and misdemeanors.

---

A CONTRIBUTION TO THE QUININE TREATMENT OF TUSSIS CONVULSIVA.

By G. THEODOR FISCHER, M.D.,

ROCHESTER, N. Y.

The number of medicaments used and recommended for pertussis is legion, and this is the best proof of the poor satisfaction that their use has given. Neither astringents nor narcotics, neither balsamies nor aromatics, neither antipyretics nor antiseptics, have been efficacious in shortening the course of whooping-cough essentially; nor, except in very few cases, have they prevented the most serious complications. I, as well as others, have occasionally observed remarkable symptomatic effects at least from the use of antipyrine. So has been and still is the treatment of whooping-cough—especially on account of the pulmonary complications—one of the most intricate problems. No wonder it is said so often: "There is no help, therefore why make unnecessary expense? The disease has to run eighteen weeks; nobody can shorten it." And is it not true that the parents are often confirmed in this opinion by their physicians, who in their skepticism are led to avoid all use of medicinal remedies and to confine themselves to hygienic treatment exclusively, except in the case of complications arising? No less an authority than Henoch said, in his Discourses on Diseases of Children: "From
treatment (i.e., of whooping-cough) you will not derive satisfactory results. A remedy to diminish the period of pertussis, especially to break off the stadium of the acute, we have not, while in the stadium decrement, when Nature begins her work of restoring, apparently almost any remedy is helpful.” Formerly I had to contend with the same difficulty as Henoch. Now, when a case of whooping-cough comes under my treatment, I take it with the positive conviction that my management will be efficacious; for there is a remedy the efficacy of which is beyond doubt, and which, taken in any stage of pertussis, produces excellent effect. It is quinine, “that pearl of our pharmacopoeia,” as Baron says, “which in its favorable influence on whooping-cough gives another proof of the variety of its uses.” Quinine was used for pertussis a long time ago, but after a season its employment was discontinued, until Binz, in 1868, called the attention of the profession to it. The results were variable, depending perhaps on the size of the dose, perhaps on the perseverance of the physician. So the full value of quinine was never realized. To what extent quinine has been used for whooping-cough in this country I am unable to state; but I have gathered the impression, after living about two years in the United States of America, that it is not administered very much in the disease in question. The merit of having placed quinine in its true light before the medical profession, is due—at least in Germany—to Ungar (Deutsche medizinische Wochenschrift, 1891, No. 18) and to Baron (Berlinische klinische Wochenschrift, 1893, No. 48).

Induced by Dr. Baron’s monograph, which I read last spring, I have treated since June, 1894, twenty-seven cases of whooping-cough and have realized remarkable results. In general I have had the same experience as Dr. Baron’s, and agree with him in his deductions entirely. The success has been variable for the first few days, because in the majority of cases the patients inclined to vomiting, and so not the full quantity of quinine was absorbed. But usually on the fifth day, at latest, a decided improvement has taken place in both the veloemence and the number of attacks. The improvement once begun, rapid progress has been made. I have had opportunities of giving the medicament to three children, who were in the first stage of pertussis.

Cases I and II were those of two children of two and two and a half years of age, whose older sisters had infected them. Here one can speak positively of a breaking off of the disease, because the spells, occurring five to six times a day, after four days were diminished to two. After four days more the whooping-cough had changed to a simple bronchitis, the course of which I did not longer observe. Case III was in a child of four years, which after ten doses had so nearly recovered that the parents discontinued the remedy, especially because the child could be induced to take it only with great difficulty. A fourth case of a beginning whooping-cough took quite another course, but here there were several unfavorable circumstances. The very feeble child came under my treatment because of a very vehement gastro-enteritis, from which it had been suffering over three weeks. After three days’ treatment the child improved, but there developed by and by a whooping-cough, which two older sisters were suffering from. To make the case more aggravated, broncho-pneumonia set in on the third day, which after twelve hours snatched the child away.

This can not be imputed by any means to the inefficacy of quinine, which in so short a time could not have taken full effect; for even in complications on the part of the lungs the efficacy of quinine is supreme, and is proved by several cases of mine, among which is that of the older sister of the patient in Case IV, who had infected her little brother.

She was suffering from right broncho-pneumonia, which had developed in the second and third lobes and part of the first, when I was called to attend her and her brother, and the fever was very high. She could not be induced to take the least particle of food, and the severe coughing attacks robbed her of sleep. After four days she was nearly without fever, had some appetite, and slept again. The spells, more than thirty a day at first, had, when her brother died, decreased to about ten, and a good expectation had taken place. Later the convalescence made more and more progress, so that I could stop further quinine treatment.

The twenty-two remaining cases were of four to five weeks’ duration before they came under my treatment, except three which will be mentioned below. Four of them were complicated with broncho-pneumonia, one with gastro-enteritis. The time which it required to reduce sixteen of them to a slight bronchitis was on an average thirteen days, while mostly from the fourth day a decidedly favorable effect of quinine was noticed. The catarrh of the bronchial tubes ceased after ten to twelve days more, and a relapse did not occur, if I may rely on the statement of the nurses.

I recollect especially one case, that of a child of one year, where the whooping-cough was already of ten weeks’ standing, the spells being very numerous and exhausting. A broncho-pneumonia did not exist, but the child had not the least appetite, and was very restless during the night. In a week the attacks were considerably diminished, and at the end of a second week only an occasional slight cough reminded the parents of the long sorrowful time past. The remaining cases were in patients who called at my office, and as I did not see them again I am unable to state the effect of quinine in these instances.

The above-mentioned exceptions, being in children of six, four, and two years of age, are the only cases where I have had to discontinue quinine treatment. They were in the same family, the disease of the two older children running over three months, while the youngest child had been suffering but three weeks. Cases I and II were complicated with broncho-pneumonia; all three of the patients had more or less fever, running sometimes as high as 102° F. I administered quinine in a powder and in a solution, gave it in amyllum capsules, and tried bread pills, but failed.*

* A form in which quinine has been administered also is that of hypodermic injection. In 1872, 1880, and 1887 some Italian and French investigators (Galigani, Schivardi, Beurnmann, Villejean) recommended very highly the use of quinine bisulphate for this purpose. In Germany, Holland in 1891, and lately Langen in 1894, also published their experience with the hypodermic administration of the same alkaloid, and, although they repeatedly had caused abscesses, even gangrenous necrosis of the skin, they came to the conclusion that it should be used in that form when it was impossible to give quinine in any other—a suggestion which surely is worth the trial.
Every dose given was immediately followed by vomiting, although I tried to give a mixture of hydrochloric acid right after the remedy. This state having continued for four days, I was compelled to stop quinine and to administer a solution of antipyrine, with the result that in two weeks the children were nearly well—by the bye, the only cases where I noticed such a prompt effect of antipyrine.

As to the doses I gave after Baron, one centigramme (a sixth of a grain) for the mouth, one decigramme (a grain and two thirds) for the year of every patient, the highest single dose not exceeding four decigrammes (six grains and two thirds), either the hydrochloride or the sulphate of quinine (the latter being much cheaper), in the form of a powder, three times a day (6 a.m., 2 p.m., 10 p.m.). In spite of the comparatively large doses the medicament agreed with the children very well, and was taken without much resistance, except in the above-mentioned cases. When an apparent improvement has taken place the dose is given less frequently, then diminished, and lastly only one full dose administered in the evening. Older children have to take the powder in amylum capsules, while little children take them without any integument. Sometimes, if the appetite is not improved as one would wish, a solution of hydrochloric acid is given additionally.

Summing up the results I have obtained in the quinine treatment of pertussis, I come to the conclusion that quinine, given in the proper doses, is the best remedy for whooping-cough at present known.

1. It diminishes the number of attacks essentially in five days at latest.
2. It reduces even the most vehement whooping-cough to a mild bronchitis in twelve to fifteen days.
3. It influences most favorably a possibly existing broncho-pneumonia.
4. It often stimulates the appetite.

If these lines induce practitioners who have with more or less success prescribed other medicaments to give quinine a trial, they will have succeeded in their purpose; and I am convinced the results will give to both physicians and patients complete satisfaction.

54 North Clinton Street.

PNEUMONIA:
ITS TREATMENT AND ITS RELATION TO LA GRIPPE.

By J. LINDSAY PORTEOUS, M.D.,
PHYSICIAN TO ST. JOSEPH'S HOSPITAL, YONKERS, N. Y.

In the following remarks I do not imagine that I can advance many or any new theories, but wish rather to urge the strict observance of a practical and successful line of treatment (founded on a perfectly logical and scientific basis) of this much-dreaded disease, and to point out some of its aspects in relation to epidemic influenza. In a comparatively short time I have had under my charge fifty cases of pneumonia. In twenty-six of these, both lungs were involved. All recovered.

When an intern in the Royal Infirmary of Edinburgh, I well remember that a hundred and three consecutive cases ended in recovery under the treatment of Dr. Hughes Bennett. His was known as the restorative system of treatment. In those days the mind of the young physician was not distracted by the stream of baneful antipyretics which now flood the therapeutic market, and to this fact, to a certain degree, the treatment adopted by Bennett compares most favorably with the treatment of many of the younger physicians of the present day. Tartar emetic was the febrifuge which was most generally used, but very rarely administered by Bennett. He relied on stimulants, not necessarily of an alcoholic nature, but good, reliable heart strengtheners; and although science has made immense strides to aid us in diagnosticing disease, and bacteriology has suddenly jumped to the forefront to assist us to come to a positive conclusion as to the immediate cause of disease, still we are in the dark as to a sure and safe remedy for many of the most common ills to which humanity is heir. We would fain hope that diphtheria antitoxine is a true antidote for the Loeffler bacillus; that tetanus antitoxine will destroy the terrors of that disease; and that the newest antitoxine—that of pneumonia—may prove inimical to the bacillus of Friedländer.

Long ago Skoda showed that pneumonia tended to resolution and not to dissolution, and such undoubtedly is the case, whether the disease is epidemic or isolated. In our treatment we must try to assist resolution and prevent dissolution. Pain, high fever, dyspnea, and cardiac insufficiency are the evils with which we have to contend, and to prevent or modify these must be our endeavor. Whether death comes from sudden syncope, pulmonary edema, or gradual sinking, cardiac failure is the ultimate ending. Recognizing this to be true, we must from the outset avoid everything which tends to weaken the patient—such as antipyretics and purgatives. The former are dangerous on account of their depressing effects. The latter are exhausting, and certainly have no power to remove the fur from the tongue. The subacral condition will cease when the temperature falls, and not till then. No amount of purgation will alter it. Let us now consider the best means of combating the tendency to cardiac failure and aiding Nature to withstand the onslaught of the bacilli till we can find a bactericide powerful enough to destroy the bacilli without injuring the patient.

The drugs upon which we pin our faith are digitalis, chloral, and ammonia. The first of these was in much favor several years ago, but in time shared the fate of all remedies which are used indiscriminately by those who have not studied the actions of them from a scientific point of view. Because large doses of digitalis cause the pulse to become feeble and irregular, in proportion to the fall of temperature, it was erroneously considered that it weakened the heart and ought not to be used in pneumonia. To those who have studied toxicology, these symptoms will be readily recognized as the toxic effects of the drug, which could happen to any one in health who has taken large doses. When using large doses, the physician must ever be on the lookout for toxic symptoms, whether they be hiccough, vomiting, stupor, or partial collapse, and lessen the dose or stop the medicine entirely till
these disagreeable results disappear, or, better still, according to Traube, stop the drug before the crisis is expected. Experience alone can teach the physician the proper dose for each individual case. We believe that want of sufficient care and insufficient experience are in a great measure to blame for the disuse or loss of confidence in the drug in pneumonia cases.

As regards ammonia in the disease, we consider that in this drug we have a valuable, quick, and powerful diffusible stimulant. It produces an increase in the force of the pulse, and is a heart stimulant. I have seen wonderfully quick results from it when the patient showed a tendency to faint, or in dyspnea.

Other conditions besides high temperature and excessive consolidation have to be encountered in pneumonia. Among these are pain, cough, and insomnia. Opium or morphine given hypodermically has long been used to accomplish this end, which, to a certain extent, it does, but to counterbalance this good work it also may produce grave results by arresting expectoration. Chlorofrom has found strong advocates for this purpose in Wuecherer, Baumgarten, and other German authorities; and well it may, as in their hands the mortality was only 3 3/4 per cent. in three hundred and three cases. It was given by inhalation every two hours. This treatment, however, would be rather dangerous in the hands of friends, or even of the majority of nurses. Liebreich discovered chloral, which has proved one of the most valuable drugs we possess. Ringler says it produces sleep and slows the pulse. By causing the patient's strength is preserved. Pain, another source of exhaustion, is relieved by it. Its paralyzing action upon the vaso-motor centers causes the heart to go slower. It has analgetic effects upon the terminal filaments. If the dose is not sufficiently large to produce profound narcotism, there can be no hindrance to the vegetative functions, consequently cellular activity is allowed to proceed. The arterioles are dilated, the free-flowing blood flushes away the static elements, the waste products being taken up by the blood-corpuscles, and leucocytosis proceeds in the regular manner. With regard to this result Auleh says: "The reserve multinuclear cells are to be found in the pulmonary structures, and when the circulatory apparatus is relieved of its heightened tension these cells are permitted to act energetically—that is, they produce nuclein, the natural antiseptic of the organism." I have already stated that pneumonia is a restorative reaction to an injury received. Such being the case, the action of chloral may modify these reactions and check wholly or in part the series of organic changes through which diseased action, when unmodified, must run; but if, on the other hand, as is probably the case, the disease is due to a microbe, the fact of the arterial tension being relieved and the resulting flushing with phagocytes must tend to cut short the disease by destroying the cause. Among the fifty consecutive cases I have referred to, the ages ranged from four months to seventy-three years. The youngest and the oldest were among those who had double pneumonia.

I need not go into detail regarding the different patients further than to mention that the temperature in different cases and at different times varied from 100° up to 105 1/2; this latter temperature was in a child aged three years. One very interesting case was that of a child aged two years and a half. It presented all the characteristics of intermittent or remittent pneumonia, with the difference that the physical signs were limited to the circumscribed patches about the size of a half-dollar, which went through the usual stages of fine crepitation, then the stage of hepatisation, increased vocal fremitus, etc., found in all well-marked cases of pneumonia. The temperature would become normal, also the respiration. Suddenly there was a rise of temperature, which at first was difficult to account for. Careful and minute auscultation and percussion revealed another spot affected. This happened four different times. This, of course, was extremely wearing, but, with the addition of a little whisky and milk, the remedies already mentioned sustained the child's strength till Nature worked a cure.

During the present and recent epidemics of influenza I have noticed that pneumonia, more or less severe, often seizes the patient, and not only that, but that it seems to be of a contagious nature. On several occasions I have had more than one in a family ill with it at the same time. During the latter part of January I had what seems to me a very good example of this. A boy, aged eight years, was seized with pneumonia in his left lung after a slight attack of la grippe. He went through the usual stages, and while he was yet convalescent his sister, aged fourteen years, who had been sleeping in the same room with him, had a violent chill and soon pneumonia developed, first in the right lung, then in the left. Both patients recovered. This certainly points to the contagiousness of pneumonia—at least that form which accompanies or follows influenza. Bacteriology indorses this statement. What is to prevent the bacillus of Friedländer, when dry, taking wings to itself and flying into the mouths or nostrils of those in the sick chamber, and like other bacilli, when a suitable hatching ground is found, multiplying and poisoning the unfortunate and unwilling recipient and guardian of its microbic rites?

There is, I think, little doubt but that pneumonia is contagious. Klein found the bacillus of Friedländer in the spuita of patients suffering from pneumonia after influenza. This points to the fact that there is some kind of an alliance between epidemic pneumonia and la grippe, or that, seeing there are so many cases of pneumonia with or following la grippe, we may presume either that the same conditions of body are favorable to both or that influenza acts upon the body in such a way that it is rendered more susceptible to the ravages of pneumonia. The persistent cough following in the wake of influenza is, no doubt, due to the Bacillus influenza irritating the air-passages. If these enter the lung tissue their constant irritation may make a condition more favorable to pneumonia than if they had not entered. Whether pneumonia is a specific fever, locally manifested by an inflamed condition of the lung, or whether it is a localized disease followed by general blood-poisoning symptoms, I think there is no doubt of its contagiousness, and therefore means ought to be
taken to isolate the patient and disinfect the spuva and clothes which have come in contact with him.

In the foregoing remarks I have endeavored to show that pneumonia certainly tends to resolution; that we must endeavor to prevent cardiac failure, and that we must admit that we can not cure the disease, but can only assist Nature to do so. Until pneumonia antitoxine has been proved to arrest the action of the bacilli Friedland we must rely upon cardiac and diffusible stimulants to support the general strength and some form of anodyne to relieve the pain. I think that a record of fifty consecutive cases brought to a successful termination by a treatment based upon this theory is much in its favor. I maintain that the treatment must not be given at haphazard, but carefully and intelligently. The size of the dose can only be arrived at after careful examination of the condition of the patient and his ability to stand it.

THE HUMAN BODY AGAINST ATHEISM.*

By E. S. MAXSON, M.D.,
SYRACUSE, N. Y.

Mr. President and Fellows of the Academy: The subject that I have chosen is somewhat out of the ordinary line of topics presented here, yet I trust that the digression should not meet with disapproval.

I believe that the atheist carries in his own person the refutation of the philosophy that he professes to hold.

We know intuitively that every effect must have a cause.

It also appears that a design must necessitate a designer. Let us consider some of the evidences of design presented by the human body.

In the first place, it is a noteworthy fact that man is in a large measure made up double—that is, he has two eyes, two arms, two lungs, and so on. In this we see an evidence both of design and of wisdom in the Designer. Normally, this double arrangement, of course, renders the body more efficient. At the same time it affords a wise provision, for on all sides we meet with cases where one member or one organ has been destroyed or disabled while its mate still remains of service. Thus one kidney is sometimes found doing the work of two.

The circulatory system furnishes many evidences of design. The arteries supplying the fingers were not placed on the front side or the back side of those members, where a sharp instrument would be most likely to sever them, but they were placed at the sides of the fingers where there would be the greatest protection possible.

While some exceptions are found, the uniformity in the position of blood-vessels in different individuals is quite notable; thus the surgeon is able to use his knife with a good degree of certainty. If the blood-vessels were distributed in an accidental way, with each person a law to himself, the surgeon might plunge his lancet into an artery instead of into an abscess. The anastomosis of the arteries was another wise provision, making possible collateral cir-

* Read before the Syracuse Academy of Medicine, November 20, 1894.

culation in case the blood supply through one artery should be cut off.

It was something more than chance, also, that placed more valves in the veins of the lower extremities than in the veins of the upper extremities.

In the blood's property of coagulation we find a great provision for the preservation of life.

Then, again, the arrest of the heart's action might have been placed under control of the will; but, in that case, it is possible that the number of suicides would be much greater.

The bones of the body are constructed in such a way as to be at the same time both light and strong. The ribs serve as a wall and defense to the heart and lungs, while the bones of the pelvis are well adapted to support the abdominal viscera.

If the human body were without a designer, why might we not find the incisor teeth set in the back part of the jaws and the molar teeth in front?

Then, again, chance might have placed hinge joints, instead of the ball-and-socket joint, at the shoulders. In this also we may be thankful that some thought was used in planning the human frame.

The hardest substance in the body, the dentin of the teeth, was placed just where it was needed.

The skin in the palm of the hand was made thicker than the skin of the eyelids.

The tactile corpuscles were placed on the palmar side of the fingers because they would be needed there.

The reflex action of the spinal cord is of great importance in protecting the body from injury. Also it should be a cause of thankfulness that the brain is normally one of the last organs to undergo atrophy from senile change.

It is desirable that deglutition may be performed in many cases where conscious sensibility and voluntary power have disappeared. Hence the act of swallowing was placed under control of the medulla rather than under control of the cerebral hemispheres. Also the protection of the glottis in deglutition is something that all can appreciate.

The eye and the ear both speak of a Creator.

He who designed the drum of the ear understood that there should be a vent to the drum, and hence we find the Eustachian tube. The external ear might have been made to consist merely of the auditory canal, yet we can not help appreciating the purpose and advantage of the cartilaginous expansion forming the auricle.

Then we have the eyeball, with its firm sclerotic coat, its hornlike window in front, its iris to regulate the amount of light, its chamber darkened with the choroidal coat to prevent reflections, the retina for the reception of luminous rays, and the lens by which the perception of the form and outline of objects is rendered possible.

And so, for a long time, one might continue to bring forward evidences of design as shown by the human body. The evidence is sufficient to prove the existence of the Creator, the First Great Cause.

In the world there are atheists, and probably still more agnostics. The atheist does not believe in a God; the agnostic does not dare assert his existence; but the human body declares that there is a God.
THE LOOMIS MEMORIAL MEETING.

This seems an appropriate title by which to mention last week's general meeting of the New York Academy of Medicine, and it was a very proper sort of meeting to be held. The academy had recently lost a member who not long before his death had served two terms as its president, by whose energy and liberality it had greatly profited, and by whose participation in its debates its proceedings had for many years been notably enriched. The loss of an individual member sometimes counts for a good deal in determining whether a corporate body is to do active and significant work or is to go on simply existing. Of course, in the case of so large and well-constituted an organization as the academy, almost any loss is certain to be repaired within a reasonably short time, but this consideration is no warrant for undervaluing past services or for failing to acknowledge openly and freely how much the common cause has been helped along by the departed.

It was fitting that Dr. Loomis’s memory should be honored as it has been honored, but it is not on that account alone that the arrangement of such a meeting was desirable; it is of direct and palpable benefit to the younger members of the academy to listen to such tributes as were paid to the distinguished dead on the occasion in question, for it gives them a livelier sense of the possibilities open to all of them and teaches them what the conduct is by which they may hope to realize those possibilities. Dr. Loomis’s success as a physician and as a teacher was in no wise due to chance or to any adventitious guidance or assistance, but to his own deeds done in conformity to plans conceived and elaborated by himself. It is in this way that, with very few exceptions, every man has to make his way in the world, unless, indeed, that way has been cleared and pointed out to him beforehand. This can not be too often or too forcibly impressed upon young men, and they are never too young to profit by it. Moreover, those who are still struggling, perhaps almost on the point of giving up, may take fresh heart when they hear such achievements as Dr. Loomis’s recounted. It is true, they can not all hope to equal or even approach them, but they can obtain a clearer vision of what it is they are striving after and of the way in which their efforts should be directed. Surely no overworked and underpaid young doctor can have gone home from that meeting without feeling somewhat encouraged, and encouragement is often the one thing needed to lead on to success. Dr. Bryant, the president of the academy, did not only a gracious but an exceedingly useful thing, it seems to us, when he planned the academy’s last meeting.

THE PHYSIOLOGICAL FACTORS OF THE FUNCTIONAL NERVOUS DISEASES OF CHILDHOOD.

In the May number of the Archives of Pediatrics Dr. B. K. Rachford writes of the blood changes which are related to neurotic disease. The most important of these are the presence of bacterial or other toxines in the blood, a venous condition of the blood, and an impoverished condition of the blood. These changes do not as a rule exist separately, but form that complicated condition called chronic anemia. Toxines, notably those of tuberculosis, diphtheria, and typhoid fever, may produce most profound nervous symptoms by their direct action. The author discusses chiefly, however, those intoxications which result from chronic microbial diseases. Chronic glandular tuberculosis he believes is the most commonly associated with these nervous affections of childhood. Hysteria, enuresis, night terrors, and chorea are frequently relieved by treating the tubercular condition. They are undoubtedly due to the direct action of some poison generated by the bacteria. The malarial toxines also are potent in producing the same series of symptoms. Chronic intestinal fermentation, too, is a frequent exciting cause of these neuroses. The continued absorption from day to day of small quantities of bacterial poisons from the intestinal canal is a very important and much underestimated cause of neurotic disease in children. Many of the nervous disorders of childhood may be relieved or entirely cured by the proper use of cathartics and intestinal antisepsites, together with a proper regulation of the diet. Self-intoxication, though important in producing nervous disease, is but little understood. The author believes that the effect of uric acid as an agent capable of producing migraine and various convulsive disorders has been greatly overestimated. The cause of these disorders which occur with a uric-acid diathesis which is marked by an increase of uric acid and a decrease of urea in the urine, he believes, must be sought for in other poisonous products of retrograde tissue metamorphosis. He calls special attention to the influence of paraxanthin and other leucomaines in producing these symptoms. After extensive observation and study the author believes that there are three distinct types of leucomaine poisoning—viz., gastric neurosis, migraine, and migrainous epilepsy.

THE AMERICAN MEDICAL ASSOCIATION.

As we expected, the Baltimore meeting which has been in progress this week was largely attended, and it is particularly gratifying to be able to add that the attendance from the Western States was noticeably large. That the president should advocate the scheme for a national bureau of health was to be looked for. Efforts to have the general meeting take some action in regard to a dispute that has long been going on as to the propriety of the association’s Journal accepting certain advertisements resulted in failure, but the votes on some of the motions were close. An important action taken was that of adopting a resolution requesting Congress to remedy the disabilities of the medical corps of the navy. It is to be hoped that this will have some effect, but we believe that individual effort with congressmen would have more. Substantial additions to the Rush monument fund were announced, and perhaps it may be said that this fund is increasing as fast as the financial depression in the community, felt most acutely by the medical profession, will admit of. It was many years since the association had met in Baltimore; we hope its next meeting in that attractive city will not be preceded by such a long period.
ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 7, 1895:

The American Pediatric Society will hold its seventh annual meeting at the Virginia Hot Springs on May 27th, 28th, and 29th, under the presidency of Dr. F. Forchheimer, of Cincinnati. The preliminary programme includes the following papers: Cerebro-spinal Meningitis in an Infant Six Days Old, by Dr. T. M. Rotch, of Boston; Three Cases of Purulent Otitis Media which ended fatally, by Dr. W. F. Lockwood, of Baltimore; Propyoneumothorax, by Dr. Walter L. Carr; Traumatic Aphasia, Scarlatina Anginosis, Croupous Pneumonia, by Dr. Samuel S. Adans, of Washington; Hyperpyrexia, by Dr. Henry D. Chapin, of New York; Sarcoma of the Kidney in an Infant, by Dr. J. Henry Fruitnight, of New York; Lymphosarcoma of the Spleen, by Dr. George N. Acker, of Washington; Tetanus Neonatorum, by Dr. J. Lewis Smith, of New York; Infantile Tetany, by Dr. M. P. Hatfield, of Chicago; Two Cases of Tetany, by Dr. Floyd M. Crandall, of New York; Amyloid Disease in Children, by Dr. B. K. Rachford, of Cincinnati; Typhoid Fever in Infants under Two Years, by Dr. William Perry Northrup, of New York; Some Forms of Eruption simulating Scarlatina, by Dr. A. D. Blackader, of Montreal; Scarlatiform Exanthem, by Dr. C. G. Jennings, of Detroit; Scarlatina with Intensified Eruption and poorly marked Constitutional Symptoms, by Dr. Louis Starr, of Philadelphia; Extensive Gangrene following Scarlatina, by Dr. James C. Wilson, of Philadelphia; Difficulty in Differential Diagnosis, by Dr. J. P. Crozier Griffith, of Philadelphia; Local Treatment of the Skin in the Eruptive Fevers of Childhood, by Dr. A. Seibert, of New York; Cases of Adherent Pericardium in Children, with Enormous Heart Hypertrophy, and Chronic Proliferative Peritonitis, and Recurring Ascites, by Dr. William Osler, of Baltimore; Rupture of the Bladder, by Dr. John Dornin; Cardiac Anomalies, by Dr. William Osler; Aorta Arising from the Right Ventricle, by Dr. George N. Acker, of Washington; Patent Ventricular Septum, by Dr. A. Jacobi, of New York; The Characteristic Features of the Recent Epidemic of Gripe, discussed by Dr. L. Emmett Holt, Dr. W. P. Northrup, Dr. Henry D. Chapin, and Dr. A. D. Blackader; Antitoxin in Diphtheria, by Dr. F. Gordon Morrill, of Boston; Personal Experience with Diphtheria Antitoxin and Blood-serum Injections, by Dr. Augustus Callé, of New York; The Value of Diphtheria Antitoxin, and its Toxic After-effects, by Dr. A. Seibert; Cases apparently of Diphtheria, but in which the Diphtheria Bacillus is not found, by Dr. E. M. Buckingham, of Boston; and Cases of Scurvy, by Dr. A. Jacobi.

Dr. Armstrong's Case of Large Vesical Calculus.—Dr. W. S. Armstrong, of Atlanta, informs us that the stone mentioned in our issue for April 27th as having been removed by him really weighed thirteen ounces and three quarters, instead of thirteen ounces and a half.

The New York Neurological Society.—The special order for the last meeting, on Tuesday evening, the 7th inst., was a paper entitled A Report of a Case of Lead Paralysis, with Special Reference to Cytological Changes in the Nervous System and the Distribution of the Lead, by Dr. C. A. Herter and Dr. Ira Van Gieson.

The Connecticut Medical Society will hold its one-hundred-and-third annual meeting in Hartford on Wednesday and Thursday, the 23rd and 23d inst., instead of as previously announced in this journal.

The New York Hospital.—Dr. Henry P. Loomis has been appointed an attending physician to the hospital, to fill the place made vacant by Dr. William Gilman Thompson's resignation.

The University of the City of New York.—The fifty-fourth annual commencement of the Medical Department was held in Carnegie Music Hall on Tuesday evening, May 7th.

Mount Sinai Hospital.—Dr. F. S. Mandlebaum has been appointed pathologist to the hospital.

Changes of Address.—Dr. William S. Dennett, to No. 8 East Forty-ninth Street, New York; Dr. Justin Herold, to No. 173 East Eightieth Street, New York; Dr. S. S. Jones, to No. 712 Madison Avenue, New York; Dr. Samuel E. Milliken, to No. 72 West Forty-ninth Street, New York; Dr. Chalmers Sangree, to No. 1531 Madison Avenue, New York.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending May 4, 1895:

ALTER, W., Passed Assistant Surgeon. Detached from the New York Naval Hospital and ordered to the U. S. Steamer Richmond.

BEYER, H. G., Surgeon. Detached from the Naval Academy and ordered to the U. S. Steamer Monongahela.

BOYD, Robert, Assistant Surgeon. Detached from the Philadelphia Naval Hospital and ordered to the U. S. Steamer Monongahela.

EDGAR, J. M., Passed Assistant Surgeon. Detached from the U. S. Steamer Richmond and ordered to the School-ship Saratoga.

MEANS, V. C. B., Passed Assistant Surgeon. Detached from the U. S. Steamer Saratoga and ordered to the New York Hospital.

MORES, Lewis, Assistant Surgeon. Ordered to the Philadelphia Naval Hospital.

STIFF, E. C., Passed Assistant Surgeon. Detached from the U. S. Steamer Chicago and ordered to the Nicaragua Canal Board for inspection of work on the isthmus.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending April 30, 1895:

HAMILTON, J. B., Surgeon. Granted leave of absence for twelve days. April 20, 1895.

STONE, G. W., Surgeon. Detailed to represent the service at the meeting of the American Medical Association. April 25, 1895.

MEAD, F. W., Surgeon. Detailed as chairman of the board for the physical examination of officers of the Revenue Cutter Service. April 17, 1895.

BANKS, C. E., Passed Assistant Surgeon. When relieved, to re-
port at the bureau for duty as chief of the purveying division. April 24, 1895. Granted leave of absence for fourteen days. April 29, 1895.

WILLIAMS, L. L., Passed Assistant Surgeon. Detailed for duty on board for examination of officers of the Revenue Cutter Service. April 17, 1895.

McINTOSH, W. P., Passed Assistant Surgeon. Detailed for duty on board for examination of officers of the Revenue Cutter Service. April 17, 1895.

KINYOU, J. J., Passed Assistant Surgeon. Detailed to represent the service at the meeting of the American Medical Association. April 23, 1895.

WOODBARD, R. M., Passed Assistant Surgeon. To proceed to Ashtabula, Ohio, as inspector. April 19, 1895.

WEINTENAKER, C. P., Passed Assistant Surgeon. Granted leave of absence for ten days. April 16, 1895.

BROWN, B. W., Passed Assistant Surgeon. Detailed as recorder of the board for the physical examination of officers of the Revenue Cutter Service. April 17, 1895. Granted leave of absence for twenty days. April 23, 1895.

STEWART, W. J., Assistant Surgeon. To rejoin station at Washington, D. C. April 29, 1895.

PROCHAZKA, Emil, Assistant Surgeon. To proceed to Evansville, Ind., for temporary duty. April 29, 1895.

THOMAS, A. R., Assistant Surgeon. Granted leave of absence for thirty days. April 19, 1895.

Society Meetings for the Coming Week:

MONDAY, May 13th: New York Academy of Medicine (Section in General Surgery); New York Academy of Sciences (Section in Chemistry and Technology); New York Medical Historical Society (private); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

TUESDAY, May 14th: Illinois State Medical Society (first day—Springfield); North Carolina State Medical Society (first day—Goldsboro); New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Albany (annual), Delaware (annual), Greene (annual—Cairo), Onondaga (annual—Syracuse), Rensselaer, Schenectady (annual), and Steuben (annual), N. Y.; Newark, N. J. (private), and Trenton, N. J., Medical Associations; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Camden (annual—Camden), Morris (annual), and Sussex (annual), N. J., County Medical Societies; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Ky.; Norfolk, Mass., District Medical Society (election—Hyde Park); Franklin, Vt., Medical Association (annual).

WEDNESDAY, May 15th: Ohio State Medical Society (first day—Columbus); Illinois State Medical Society (second day); North Carolina State Medical Society (second day); Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

THURSDAY, May 16th: Ohio State Medical Society (second day); Illinois State Medical Society (third day); North Carolina State Medical Society (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, May 17th: Ohio State Medical Society (third day); New York Academy of Medicine (Section in Orthopaedic Surgery); Baltimore Clinical Society; Chicago Gynecological Society.

Saturdays, May 18th: Clinical Society of the New York Post-graduate Medical School and Hospital.

Births, Marriages, and Deaths.

MARRIED.

Banks—Clough.—In Natchez, Miss., on Tuesday, April 30th, Dr. J. E. Banks, of Monticello, Miss., and Miss Loula Clough, of Natchez.

Boyd—Williamson.—In Darlington, S. C., on Tuesday, April 23d, Dr. John E. Boyd and Miss Besie Williamson.

Jameson—Williams.—In Baldwinville, N. Y., on Tuesday, April 30th, Dr. Thomas Jameson, of Rochester, and Miss Clara Williams.

Leigh—Hyams.—In Port Allen, La., on Tuesday, April 30th, Dr. Aleide Leigh, of Perthshire, Miss., and Miss Julia T. Hyams.

Pierce—Morton.—In Milwaukee, on Thursday, April 25th, Dr. Norval H. Pierce, of Chicago, and Miss Drucé Wali Morton.

DIED.

Allen.—In New York, on Thursday, May 2d, Dr. Harlan Preston Allen, of Columbus, Ohio.

Burt.—In Bay Shore, N. Y., on Sunday, April 28th, Dr. Matthew H. Burton.

Byron.—In New York, on Wednesday, May 8th, Dr. John M. Byron, aged thirty-three years.

Cupples.—In San Antonio, Texas, on Friday, April 19th, Dr. George Cupples, aged seventy-nine years.

Frech.—In Malden, Mass., on Saturday, April 27th, Dr. Nathan Frech, aged eighty-four years.

Fuller.—In Brooklyn, on Thursday, May 2d, Dr. Stephen Edward Fuller, aged fifty-eight years.

Greely.—In South Weymouth, Mass., on Tuesday, April 23d, Dr. Moses R. Greely, aged sixty-seven years.

Ison.—In Oxford, Miss., on Thursday, April 25th, Dr. T. D. Ison, Jr.

Letters to the Editor.

THE ALLEGED GLOBLICIDAL EFFECT OF ALIEN SERUM.

NEW YORK, May 6, 1895.

To the Editor of the New York Medical Journal:

Sir: With reference to the second letter of Dr. Armstrong in the last issue of the Journal (May 4th), permit me, first, to state briefly the exact point under discussion.

Dr. Armstrong maintained in his first letter (April 13th) that in the consideration of the use of antitoxine serum the factor of the globlicidal effect of alien serum was overlooked, and that it was this factor which caused the death of the seventeen-year old girl in Brooklyn. In my letter (April 27th) I pointed out that all the statements as to the globlicidal effect of alien serum had reference only to its intravenous transfusion and not to its subcutaneous injection; on the contrary, many subcutaneous injections have now been made with horse serum into rabbits and guinea-pigs with no globlicidal effects; and, finally, that with such a small quantity as ten grammes of horse serum the globlicidal effect would have no fatal consequence
even by intravenous injection. Now let us see the answer of Dr. Armstrong. He says that I misunderstood his position when I considered that he confounded intravenous with hypodermic injection. "Morphine or any other drug acts more decidedly and rapidly if injected into a vessel rather than beneath the skin, but its ultimate effect is the same. So with serum." Accordingly Dr. Armstrong makes no distinction between intravenous and hypodermic injections. Where, then, did I misunderstand him? Perhaps in my statement that he unconsciously confounded both methods. But I had sufficient reason for such an assumption. Dr. Armstrong himself states that intravenous injections act "more decidedly and rapidly" than hypodermic applications. Under such circumstances an experiment which is made with intravenous injections is certainly not implicitly applicable to hypodermic injections. Dr. Armstrong's quotation in the first letter, however, had reference only to transfusion, and there was no expressed statement whatsoever that he believed those experiments to hold good also for hypodermic injections. Hence my assumption that he was "not conscious of the fact that he is confounding intravenous with hypodermic injections" This is, however, an indifferent matter. There can be no misunderstanding about his present position. He says that there is no difference in the ultimate effect of morphine or any other drug after the two modes of administration. "So with serum." Morphine was an unhappy selection for comparison, as there is a special reason why the ultimate effect is the same, and that is that morphine is always exerted in the stomach and intestines, no matter where it is introduced, and it is certainly not so with serum. In order to show that there is a great deal of difference in the ultimate effect of some substances according to the mode of their introduction into the body, I need only refer to such simple media as water and milk. Their intravenous transfusion might produce death, whereas they are quite harmless fluids in hypodermic injection. But there is a still more striking instance in Dr. Armstrong's own quotations. While he does not cite anything which could be construed in favor of a globulidel effect of the subcutaneous injection of alien serum, he makes a quotation which certainly does not support his view. It reads as follows: "... they [Héricon and Richet] also showed that thirty grammes of dog's blood to each kilogramme of a rabbit might be introduced with safety into the peritoneal cavity of the latter animal, whereas if seven grammes were introduced into the veins the animal died." The rabbit with seven pro mille of alien blood injected into the veins died, and the rabbit with thirty pro mille of alien blood infused into the peritoneal cavity "lost weight during many days." Are these ultimate effects the same? By the way, a profound disturbance in the nutrition sometimes occurs also when blood of the same class of animals is injected into the peritoneal cavity—probably on account of some degree of peritonitis produced by the foreign body.

Whether the antitoxine serum produces hyperthermia or contains another toxic principle, has nothing to do with our question. Dr. Armstrong spoke in his first letter exclusively of the globulidel effect of the horse serum in the antitoxine, and only in reference to this did I say, and do I say again, that his position (in his first letter as well as in the second) is not sustained by facts; nobody as yet has maintained that a subcutaneous injection of ten grammes of alien blood or serum has a globulidel effect; on the contrary, in connection with the preparation of antitoxine, hundreds of experiments have been made which have demonstrated conclusively that the subcutaneous injection of alien serum does not have a globulidel effect even on a rabbit, the most sensitive for this purpose. In conclusion, I wish to say that I am not attacking Dr. Armstrong, but am warding off the accusation against Behring, Ehrlich, Roux, and other investigators of high merit, that they overlooked in their efforts the elementary factor of the globulidel effect of alien serum.

S. J. MELZEE, M. D.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF CHARITY HOSPITAL.

Meeting of April 3, 1895.

The President, Dr. ADELOPH LIPP, in the Chair.

Staphylorrhaphy.—Dr. CARTER S. COLE spoke of a patient whom he had hoped to show at the meeting, but who had not yet arrived. He stated that the point of interest was the age at which the operation had been done, and as to the possibility of ever doing any good in those cases; unless an operation was done at a very early age, before the child had learned to use other muscles in articulation, it was apt not to be of benefit. Any one interested in this matter who had done operative work was probably quite familiar with the difficulties of staphylorrhaphy. In the present case there had been two operations. The fissure had extended up to the posterior third of the hard palate, and the first operation had been done with the head in the upright position, the parts being sutured to the tip of the uvula. Union had occurred over only a third of the part sutured. A year later there had been much adenoïd tissue in the pharynx, which had had to be removed before the second staphylorrhaphy. Two weeks later the speaker had performed the second staphylorrhaphy, again using silk worm gut for suturing, the head pendent, loosening up the palate on either side by an incision, and relaxing the uvula as much as possible. Union had taken place to the tip of the uvula and the roof of the mouth was now perfect. The recovery had been uninterrupted and the child was improved in every particular, losing a great deal of that catarhhal voice which was so persistent in such cases.

The President asked if the hearing had been affected, and what effect the removal of the adenoids from the post-nasal space, plus the improvement due to staphylorrhaphy, had had on the hearing.

Dr. Cole stated that the hearing had been perfect all the time; the adenoids had not affected it at the time he had seen the child. It had been nearly a year between the first operation and the time he had seen the child again, and during that time the pharynx had been pretty well filled with adenoids. His impression was that the child had not been particularly bothered with catarhhal symptoms at any time.

A Sterilizer.—Dr. E. PIERRE MALETT presented a sterilizer. While claiming no originality in its conception, he had put it in a form in which for simplicity, compactness, and efficiency it equaled any, while its expense was trifling. It consisted of two tin baking pans, fourteen inches long, six inches wide, and three inches and a half high, and two small alcohol lamps which could be folded up and carried in small boxes. One pan fitted into the other when not in use, holding the instruments, and the complete apparatus, instruments and all, could be carried in a small satchel. When in use, one pan was filled with water covering the instruments, while the other was inverted upon it and pressed down tightly so as to retain the steam. The alcohol lamps were then unfolded and lighted and the pans placed upon them. After boiling as long as necessary, the inverted pan was removed and used as an instrument tray, thus assuring perfect sterilization. The cost of the entire apparatus was just seventy-one cents. It did not have to be made.
to order by a special workman, but could be bought at any hardware or large general store at the cost stated.

Dr. Cole suggested baking tins that were hinged at the side as being of advantage.

**Practical Points as to Peritonitis.—** Dr. Cole, in a paper on this subject, stated that peritonitis was the result of injury to the peritoneum itself or to neighboring structures, or of disease of one of the organs which it covered, or of the extension of disease to it from other structures. He believed it always bacterial, and he thought that no single variety of micro-organism was alone concerned in the inflammatory process. In cases of intestinal origin the colon bacillus was present, the Streptococcus pyogenes in purulent peritonitis, the Staphylococcus pyogenes aureus or albus after laparotomy, and the *Amoeba coli* in some cases of amebic dysentery, and the *Diplococcus pneumoniae* was sometimes found. The symptoms were pain, intense, cutting, piercing, gripping, intermittent, diminishing as the disease extends, with or without chill; vomiting, inceasing, intractable as the abdomen became more distended, until intestinal-peritoneal septicaemia completed the scene and destroyed the patient. As to diagnosis, the previous history, the possible origin, extent, condition, and surroundings of the patient, the determination of present or past kidney diseases, the latter having a special bearing on treatment, were all matters of grave import in making the diagnosis and directing the course to be followed. The speaker gave the following conclusions:

1. Peritonitis was palpably and practically always a symptom demanding surgical consideration, not necessarily operative interference; and in any case a man who was unable to meet any surgical aspect that might arise, did himself and his patient an injustice in not having in consultation from the outset some one who was able to do it. 2. In localized cases of pelvic origin, we should use saline cathartics, hot douches, and hot applications (cold in exceptional cases), followed later by appropriate and necessary operative treatment by the abdomen or the vagina, preferably, where practicable, the latter. 3. In cases originating in disease of the vermiform appendix, the possibility or probability of perforation should be considered, also of the existence of intestinal paresis and of the limitations of the process, and then we should make an immediate decision as to operation. Emptying the lower bowel was in all cases advisable, but saline should be used cautiously, if at all, before an operation. Morphine in small quantities was permissible if one were well assured of the existing condition. In a considerable proportion of these cases early operative interference offered the best chances. 4. In circumscribed cases, of whatever origin, where the process simply resulted in an abscess, it should be dealt with as such and surgically. 5. Rectal and vaginal examinations were not to be overlooked as important avenues leading to a diagnosis. If aspiration was permissible and desirable, an incision was demanded. 6. In a general septic peritonitis, of whatever origin, an operation alone gave any hope.

Dr. Brooks H. Wells stated that his own views coincided with the author's absolutely, both in the idea that peritonitis was always a symptom of some localized trouble, and that it very often needed surgical interference.

The President asked if Dr. Wells would say that peritonitis was always a symptom of localized trouble.

Dr. Wells stated that fifteen years ago there had been a great many varieties of peritonitis spoken of, called general peritonitis, local peritonitis, etc., but nowadays peritonitis was not regarded as a disease per se, but rather as a symptom of some previous injury or infection of the peritoneum. It was always localized at the beginning, and only became general when conditions were present which favored the spread of the initial infection.

Dr. W. L. Stowell spoke of a case of his that he considered peritonitis, and had called a consultation with the expectation of operating. The consultant, however, had thought it was better not to operate. In a few days the course of the disease had been unfavorable, and the patient had been removed to a hospital. The operation was performed, and it was found that the trouble was tubercular. In that case the operation would have been unfavorable at any time.

Dr. A. Campbell White spoke of a recent case of his of peritonitis or, more definitely speaking, inflammation of the appendix, in which he had called a consultant with different results. The speaker had not expected an operation to be performed, and on his describing the symptoms the surgeon had thought the same; but after examining the patient the surgeon had decided upon an immediate operation, and the operation had been performed as soon as the patient and instruments could be prepared. The symptom in this case indicative of operation had been a very strong muscular resistance over a somewhat restricted area just above and to the inner side of the superior iliac spine. The absence cavity had been found much higher and at some distance from the area of tenderness. The temperature had been 99°F. The patient had recovered. The point of interest he considered in this case to be the almost entire absence of constitutional symptoms, with only occasional attacks of localized pain without pressure, in a patient whose local condition had proved an operation to be of a very serious character. He believed the history of this case and the subsequent events strongly emphasized the point brought out in the paper of the evening, that we could do justice to ourselves and to our patients only by having the benefit of an early consultation in such cases.

Dr. E. P. Mallett wished to emphasize the importance of a careful examination *per rectum* and its great value as a means of diagnosis in cases of peritonitis. In five cases of appendicitis in women, diagnosed as pyosalpinx, he had been able, after a careful rectal examination (as well as bimanual palpation *per vagina*), to make a perfect diagnosis, as proved by subsequent operation. The practical point which had impressed him in the cases cited was an induration, or brawny feeling, high up on the right side of the pelvis. Whether this existed in all cases, or only in those where the appendix is low and had become attached to the surrounding tissues, he could not say.

The President said that to the surgeons was due the credit of having made our notions concerning the fact or facts of peritonitis clearer. It was interesting to look over the statistics of abdominal diseases for the years, say, prior to 1885, and the statistics of the same diseases since 1885 or 1890. One was struck by the comparative scarcity of local peritonitis, i.e., appendicitis, before 1890; now appendicitis was found and recorded more frequently because the surgeons had taught us to be better diagnosticians in this respect. However, there were certain cases of peritonitis, local in origin, which became general so quickly or killed so rapidly by shock as to be beyond remedy even by the surgeon. Possibly the facts concerning peritonitis might be still further appreciated in the near future, and the surgeon be dispensed with or his usefulness as an operator limited. He narrated the case of a man who had had symptoms of chronic lead poisoning and, as an acene trouble, colic. On the fourth or fifth day of the disease a slight swelling in the right iliac region had been noticed, and a surgeon had been called in to operate. Trouble with the appendix had been looked for from the start, but no evidences of that trouble could be found. There had been no McBurney sign at any time. The surgeon had confirmed the diagnosis, and, instead of operating, had aspirated and drawn off a large quantity of
puriform matter through the rectum. The next day the man had been operated on and a gangrenous appendix found loose in the pelvic or abdominal cavity. The patient had died about twelve hours after operation. The speaker thought the gravity of localized peritonitis in children had been exaggerated by surgeons. Every summer he was called to see boys who had localized peritonitis brought on by overexertion from swimming and ball-playing. In a week or two they recovered. He knew of several men who had had recurrent attacks of peritonitis (appendicitis) who were not confirmed invalids. He would by no means minimize the importance of the surgeon's aid in these maladies, neither would he say that all persons with localized peritonitis should be operated on.

Dr. Cole said that he did not recommend an operation in every case, but his point was that peritonitis was always secondary; that it was always a surgical disease; and that it should have associated in its care a man able to do anything that might be required in a surgical way. In the last three years he had taken through five or six cases of appendicitis without operative procedure, but where he had operated for early perforation he had had the satisfaction of finding his diagnosis correct—that the perforation had taken place. In regard to examination through the rectum, he made a special point of that in all cases. Particularly he had in mind the tube and ovary of the right side, in their relation to disease of the appendix, where the vaginal and rectal examinations were demanded. He spoke of a case where he believed that if a surgeon had been called at first the patient's life would have been saved. As to an operation for perforation in typhoid fever, he had never recommended it, but a great many cases of retroperitoneal abscess were diagnosed and treated throughout as typhoid fever. In a case he had seen and considered to be typhoid fever, after five or six weeks' illness he had found an abscess, and he had since doubted very much whether the case had been anything else than one of retroperitoneal abscess.

Malarial Fever in Infancy; its Etiology, Symptoms, and Treatment.—Dr. Charles J. Proben, in a paper on this subject, stated, as to etiology, that the two main conditions favoring malarial fever were telluric and meteorological. The only way of determining whether a location was malarial was by noting the effect of residence in it upon the human race. The severest cases were in the southern and southwestern States, the temperate zone furnishing a large number of milder cases, while the far north was practically exempt from the disease. A temperature of about 60° F. was favorable; below this there was practically no danger. Freezing destroyed the miasm. Air and water were both thought to be media for the transmission of the poison. The susceptibility was far the most marked in children from two to seven years of age. Fetal malarial disease was rare, and infants were almost exempt, because they were not exposed to the miasm after sunset, when infection oftentimes took place. Owing to the favorable telluric conditions, the absence of swamps, brought about by drainage, and the effect of population, malarial disease was seldom contracted in this city, except along the water front on the upper third, along the east side, and the middle part of the west side. The plasmodium was pathognomonic of malarial poisoning. In the human blood the hematozoon attacked and rapidly destroyed the red blood-corpuscles, producing anemia. Pigment resulted from their action on hemoglobin, producing melanemia and interfering with the oxygen-carrying function of the blood. There were different forms of the parasite—the amoeboid, rosette-shaped, crescent, and flagellate bodies and spores. Blood examinations were advised in all obscure cases of fever where chronic paludism was suspected. A good light with a one-twelfth immersion lens was necessary for the examination of the fresh blood, in order to discern the amoeboid motion. Dried specimens were not so satisfactory. The stain was preferably methylene blue or gentian violet.

The two forms were intermittent and remittent, and the latter was often mistaken for typhoid fever. There was well-marked malaise, accompanied by dryness of mouth and by a general irritable condition. The infant looked tired, its face was drawn, its color changed; the nose was pinched, with dark circles beneath the eyes; the skin was pale, often livid; the nails and finger tips were blue, or the lips were cyanotic; the surface temperature was reduced, especially in the extremities, which appeared cooler; rarely there were twitchings of the muscles or other cerebral symptoms. If the attack occurred after feeding, nausea and vomiting might occur. The pulse was rapid and the rectal temperature moderate or high, according to the severity of the case. These symptoms were followed by a febrile stage, which was the first constant and reliable condition. The phenomena during this period were great irritability, restlessness, peevishness, even capriciousness; the cheeks were flushed, the skin was hot and dry, and the lips were dry. The two great systems most affected in infants were the respiratory and the gastro-intestinal. Enlargement of the spleen should always be looked for. Of the respiratory tract, the nose might be affected, manifested by sneezing and an attack of coryza. The larynx was attacked by spasmodic or inflammatory conditions; the tonsils were the seat of congestion, with small white spots resembling follicular amygdalitis; there were also bronchitis or pulmonary congestion in infants, intermittent forms of torticolis, with or without brain complications, vaso-motor disturbances, urticaria, usually due to gastro-intestinal disturbances, herpes facialis, and in severe cases bennaturia.

Where the patient inhabited a malarial district, removal to a healthier and better-drained locality was desirable. Night exposures and a sleeping apartment near the ground were to be avoided. The drinking water, also milk, should be sterilized. Salt water bathing was to be recommended. The diet should be regulated. The great remedy was quinine or the other alkaloids of cinchona bark. Given in large doses, quinine seldom failed to effect a cure. For an infant, from four to six grains a day should be given for a week or two. To disguise its bitter taste, it could be given in powder suspended in aromatic syrup of yerba santa. We should add to the mixture small quantities of alkaline carbonates, to prevent any solvent action on the quinine. The solvent action in the stomach could be facilitated by administering immediately afterward a few drops of hydrochloric acid or a little lemon juice. Next to quinine, arsenic was the most useful drug in chronic malarial dyscrasia. It should not be given in acute intermittent fever, unless for some reason quinine could not be given. Quinine in sufficient quantities in the blood had an influence over the protoplasm of the parasite which rendered that organism inert, so that it fell a prey to the phagoocytes, giving the blood, which had become impaired, a chance to recruit new elements.

Dr. Cole said the writer of the paper had evidently found an effective method in the examination of the blood, and he hoped he would give it.

Dr. Stowell said he had had twenty-five years' experience with fever and ague, as in 1870 he had had the disease in Michigan, where it was extremely prevalent and there was every facility for developing the plasmodium. In this city the drainage was good, and the water supply and sewer system were satisfactory. He had noticed enlarged spleen in a few cases. He also examined the blood for the plasmodium, and thought fresh blood was far more satisfactory than dried blood. He thought the number of malarial cases was exaggerated, and that ninety-five per cent. of the patients had indigestion, only need-
ing a clearing out of the bowels. Where the plasmodium was found and the large spleen, quinine was the only remedy. He did not believe malarial fever was common in this city, except where there was considerable low land or land being turned up anew, as in Harlem.

The President thought there were among children a great many cases of fever of an intermittent type, due to bad air, which are cured by quinine. Why should we cease to call them malarial? In cases in which this plasmodium was found, let it go by a name that characterizes it, and then due importance from a practical as well as theoretical point of view would follow, and no exaggeration one way or the other become fixed and confusing.

Dr. George H. Mallett spoke of three cases of children who had had acute nephritis. They had all had a cold stage and the high temperature and sweating. They had been treated continuously with quinine, with no effect, until the urine had been examined, and then remedies applicable to the kidney lesion had been given with the happiest results. He thought it very important that the urine should be examined in all cases presenting these symptoms.

Dr. A. T. Mezey said that the effect of the disease on the eye was the hardest form of eye trouble he had to deal with, and the form that it usually seemed to take was keratitis, sometimes at the junction of the cornea and the sclera, but more frequently well within the cornea.

Dr. Prokyn stated that he had not met with the nephritis spoken of by a previous speaker, but he had frequently observed small quantities of album in the urine. Quinine had been used hypodermically only in cases of children very ill, where the quick action of the drug had been desired. He emphasized the importance of an examination of the blood, and said it could be made easily. A drop of blood was put on a glass slide and covered by another slide, and with a good microscope the examination would take but five minutes. If the examination could not be made at the patient's house, a drop of blood was dried thoroughly, then stained, and the examination was made afterward.

Remarks on the Aims and Methods of Hospital Alumni Societies. The President, in a paper with this heading, stated that, as this was the next to the last meeting of the society for the season, he wished to bring to the attention of the members a few facts concerning its methods of management. Too often one saw only the same faces and heard only the same voices, and under such circumstances the meetings could not help but finally become monotonous. The men who took the most interest in the meetings were those who had left the hospital between 1875 and 1885. The circle was too limited, and an effort should be made to interest those who had left the hospital before and since that time. He suggested that the committee on new members be asked to enlarge their sphere of usefulness by looking around for candidates, old practitioners as well as the younger graduate. He spoke of the necessity of each member keeping aloft on the grand stream of medical science and art and he thought alumni societies had exceptional advantages in that all their members had enjoyed the rare opportunities of observation in a large hospital before beginning their career as private practitioners; some of them had drifted into the various specialties, some were only physicians, others only surgeons, and only a few were general practitioners. Thus each could carry away more from the meetings than from the meetings of the other societies, all of which had special tendencies. He stated that by vote of the last meeting the officers and standing committees formed its executive committee. The powers conferred were great and might easily be abused, but, if properly managed, would facilitate and expedite the routine business and brighten and lengthen the social part of the gatherings. The specific character of the government of the society was committee government. He suggested that the names of all the officers and members of the various committees be printed on the reverse side of the notice cards.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of January 2, 1895.

The President, Dr. C. C. Barrows, in the Chair.

(Concluded from page 565.)

Double Castration for Hypertrophy of the Prostate; a Critical Study of the Subject from the Clinical Standpoint.

—Dr. Samuel Alexander read a paper with this title.

Dr. E. L. Keyes said that, beyond offering his moral support to the author in the position taken by him, he felt that he could do but little. Certainly some of those interested in genito-urinary surgery had been too enthusiastic when they had accepted without question the remarkable statements that had been made about atrophy of the prostate occurring within a few hours or days after castration. He had suggested the operation to three patients, all of them very old, and most of them quite feeble, who had refused to give their consent to the operation on the ground that the testicles had not yet ceased their function. The operation might be applicable in a certain class of cases, but personally he was still of the opinion that the average person with enlarged prostate was better off if properly taught and supervised in the use of the catheter. He had in some instances been able to secure the return of the entire function of the bladder when there had been absolute retention of urine, with entire dependence upon the catheter for vesical evacuation for periods as long as several weeks. This had been done by careful and persistent use of a catheter, vesical irrigation, rest, and proper dietetic and hygienic measures. He would advocate strongly the various methods of prostatectomy, adapted carefully to the individual case. Where the bladder was entirely atrophied and incapable of carrying on its normal function, the catheter must still be resorted to, even though the caliber of the prostatic urethra had been restored. There were conditions in which cathectism was very painful, or was very unsafe, owing to the patient's ignorance and uncleanliness. In cases of this kind castration might be considered justifiable, as well as in cases where, owing to the patient's general health, prostatectomy would be especially dangerous. Here it was possible that castration might accomplish a good deal, but this was a matter to be determined by further observation. In conclusion, he would say that it seemed to him that the protest against a generalization of this operation made by the author of the paper was timely and well worthy of consideration.

Dr. L. Bolton Barrows said that he had been very much pleased with the paper. In analyzing the cases already reported, he had come to about the same conclusions as the writer of the paper. It had never seemed to him that the patients who had been castrated and reported cured had been properly observed and classified before operation. A distinction must be made between the physiological atrophy of the prostate resulting from the abrogation of its sexual function, and a decrease in size of the pathological condition called hypertrophy of the prostate. This pathological condition was a hyperplasia, and it could not be that this hyperplasia would disappear within a few days after performing castration. Such a contention was preposterous. Rest in bed, with proper cathectism, was well known, would so modify the condition of the prostate as to allow much more freedom in the passage of
urine. He had proposed this operation of castration to patients, but in no case so far had they given their consent. He had been able, however, to relieve these prostaties by other methods, although, of course, not to cure them. It was an ingenious theory, based upon observations in regard to eunuchs and the lower animals, but to apply it to a pathological condition and to patients of advanced age did not seem to him at all rational.

Dr. Robert T. Morris asked if ligation of the vas deferens and seminal artery was not likely to accomplish as much as castration, although perhaps more slowly. It was known that such a ligation set up a gradual atrophy when done accidentally.

Dr. Alexander said that the question had been asked by Dr. Morris when Dr. White had read his paper before the American Association of Genito-urinary Surgeons, in Washington, last May, and the reply had been that this was a matter demanding further investigation. He knew that it produced the same result in animals as removing the testicles did.

Regarding the treatment of advanced prostatic disease by drainage, he would say that the advantages of perineal incision over suprapubic incision were great. He had not yet offered castration to any patient. In a case shown at his clinic that day, the patient, an old man of sixty-five years, had suffered from frequent micturition and other urinary symptoms for a number of years; previous unsuccessful attempts had been made to get an instrument into his bladder. The rectal examination which he had made had shown a very large prostate. Attempts to introduce any catheter had failed, owing to a stricture situated just in front of the bulbo-membranous junction. For this reason he had cut this man in the perineum on a filmous guide, had then forcibly dilated the neck of the bladder, and had found a long, rigid prostatic urethra. The bladder had been completely atrophied. A drainage tube had been introduced for about a week, and the bladder and wound washed out twice daily. A catheter had been passed twice a day. The patient had had almost complete atony, yet he could now void seven or eight ounces of urine spontaneously. When it was allowed to collect, there was the same amount of residual urine.

The speaker said he thought that in cases of difficult catheterism due to prostatic obstruction, in which prostatectomy could not be performed, there was nothing which gave more satisfactory results than this operation; he did not think its merits had been sufficiently appreciated.

Book Notices.

The publishers announce that this work will be issued in sixteen fasciculi, royal folio size, each fasciculus consisting of six full-page plates with descriptive text. The ninety-six plates will represent fully two hundred life size figures reproduced from the original water color drawings by chromolithography.

The first fasciculus contains plate ii, illustrating erythema tuberculatum of the chest and of the hand, and erythema circinatum; plate xii, illustrating dermatitis gangraenosa infantum with varicella, and miliaria infantum; plate xiii, showing ichthyosis of the trunk; plate xvi, showing four forms of xanthoma; plate lx, presenting lupus vulgaris with epithelioidea; and plate xxvi, depicting sebaceous in an infant and an adult.

In the second fasciculus, plate v shows the early and the late stage of urticaria papulosa; plate xii, three illustrations of the early and later stages of lupus vulgaris; plate lxviii, three phases of scrofuloderma, chronic scrofulous ulceration, lupus verrucosus, and verruca necrogenica; plate lxxiii, a remarkably large example of cicatricial keloid; plate lxxx, good examples of eczema-like seborrhoea and of eczema palmarum senilis; and plate lxxvii, a case of seborrhoea papulosa sen lichenoides.

Fasciculus three contains plate xxxii, that illustrates sub-acute and chronic forms of lichen planus and also its mode of affecting the mucous membrane; plate xxxvi, that shows a case of bullous iodide eruption in a patient affected with chronic albuminuria; plate xxxvii, that illustrates the early and the late stage of arsenical pigmentation, and the early and the late stage of arsenical keratoses produced in persons taking arsenic for therapeutic purposes; plate lxvii, illustrating three varieties of warts; plate lxxiv, showing an interesting case of lupus erythematosus sebaceous; and plate lxxvii, that shows examples of acne varioliformis of the face, head, and trunk.

The fourth fasciculus contains plate xv, that portrays three cases of herpes zoster in different stages; plate xlvii, that shows an extreme example of pemphigus; plate xxxviii, that depicts an example of lichen sclerosus and a case of lichen planus; plate xxxvi, that shows a confluent eruption caused by potassiuim bromide given to a child for restlessness; plate lxxxv, that shows the face and hand of a patient affected with tuberculated leprosy; and plate lxx, that illustrates a case of anaesthetic leprosy.

The fifth fasciculus contains plate xvii, that portrays an interesting case of that rare and fatal affection, pemphigus foliaceus; plate xxx, which shows a case of pityriasis rosea; plate xliv, which illustrates a case of the uncommon ichthyosis hystrix unilateralis; plate lxviii, which shows two examples, one of the band, the other of the patch, form of scrofuloderma circinatum; plate lv, which represents a case of papillary pigmented, and two views of an uncommon case of unpigmented convoluted, mole; and plate xcvii, that shows the circumscribed, the diffuse, and the kerion forms of tinea tonsurans.

The sixth fasciculus contains plate vi, which portrays a case of the nodular type of urticaria pigmentosa, that was first described under the title of xanthelasmoide; plate vii, which illustrates the vesicular and papular forms of eczema; plate xx, which depicts hydroa herpetiformis; plate xxvii, which represents psoriasis; plate lvi, that shows a case of that rare disease, xeroderma pigmentosum; and plate lxxvii, which represents a case of melanotic and one of secondary sarcoma.

In the seventh fasciculus are plate vii, illustrating prurigo; plate xiii, which shows cases of impetigo contagiosa bullosa, of impetigo contagiosa pediculio, and of that form of impetigo contagiosa called erythema; plate xiv, which represents a case of that severe and fatal disease pemphigus vegetans; plate xxvii, which shows an example of psoriasis gyrata, the lepra of Willan; plate i, which is a good representation of a case of elephantiasis tropica; and plate lii, which shows the face of a patient affected with chloasma uterinum, also her hands and forearms, that are affected with leucoderma and melanoderma.

The eighth fasciculus contains plate xvi, which portrays cases of herpes epithalmicus and of herpes febrilitis; plate xxiv, which shows acuta and chronic psoriasis; plate xxxviii, which represents two forms of skin discoloration produced by drugs, argyria and chrysarobin erythema; plate xl, which shows gangrene of the foot from cold; plate lxxi, which illustrates xanthoma
diabeticorum; and plate lxxvi, which shows several of the forms of rodent ulcer and epithelioma.

The ninth fasciculus contains plate xxi, that represents hydro-herpetiformis of the leg, the breast, and the arm, one of the illustrations showing very admirably the distinction between this disease and pemphigus, that, as the author states, probably depends upon the clinical morphology and not upon any fundamental difference in the pathology; plate xxxv, which illustrates a case of psoriasis punctata in which there was but a moderate degree of scaliness; plate xxxix, which shows a case of pityriasis rubra, the history of which is interesting because thyroid extract was given for a time with the effect of reducing the hyperemia, but in which, syphilitic infection being suspected, the patient was placed on proper treatment and a cure resulted; plate xlv, which depicts extreme forms of ichthyosis of general distribution, also four instances of keratosis; plate xlvii, which shows a case of ichthyosis congenita in a child a month old; and plate lxxv, which represents three forms of lupus erythematosus.

The great essential for an atlas of skin diseases is that the portraits shall be good, and this requisite is met in this work. The wide experience and excellent judgment of the author should be assumed to be a sufficient guarantee of the care with which the different illustrations would be selected, and this half of the work fully confirms the correctness of such an assumption. The text is short, but clear and practical, describing the details of the case, the varieties of the disease, and the methods of treatment.

A Pictorial Atlas of Skin Diseases and Syphilitic Affections in Photo-lithochromes from Models in the Museum of the St. Louis Hospital, Paris. With Explanatory Woodcuts and Text. By Ernest Besnier, Physician to the St. Louis Hospital, etc.; A. Fournier, Professor of the Faculty of Medicine, etc.; M. Tennesse, Physician to the St. Louis Hospital; M. Hallopeau, Professor agrégé of the Faculty of Medicine, etc.; M. Du Castel, Physician to the St. Louis Hospital. With the Co-operation of Henri Feulard, Curator of the Museum, and Léon Jacquet, Secretary of the Dermatological Society of France. Authorized English Translation. Edited by J. J. Pringle, M.B., F.R.C.P., Assistant Physician to and Physician to the Department for Diseases of the Skin at the Middelses Hospital, London. Part I. London: F. J. Rehmum, 1895. [Price, 10s. 6d.]

The Publishers state that this atlas is intended as a pictorial representation of several of the famous models of dermatological and syphilitic cases made by Baretta for the St. Louis Hospital, of Paris, representing typical cases of common diseases. For the better understanding of the plates these will be reproduced in woodcuts by photo-lithography. The editor states that he will confine his annotations to questions of nomenclature; his principal effort will be to insure the accuracy of the English translation.

The plates in this part illustrate agminate lupus vulgaris of the center of the face, dermatitis herpetiformis, vulvar syphilitic chancre, and patchy purpuric erythema appearing in successive crops. These plates are beautifully colored reproductions of the models; and the text, in each case signed by the author, describes the condition, gives a history of the case, and refers to the symptomatology, diagnosis, and methods of treatment.

The work promises to be a very useful contribution to the illustrated literature of skin diseases.

We would advise the publishers, in mailing the plates, to protect them so that they can not be bent by folding, thus spoiling the appearance of the plates.

This collection of diet lists and the accompanying sick-room dietary is a convenience that will be appreciated by the physician, who is so often asked what his patient may eat. A suitable form is torn off, additions or alterations may be made if required, and with little trouble the patient's want is supplied.

Human, like other things, has its varieties, and in the wide range between that of Rabelais and of Jerome K. Jerome, for example, there is a field that may be filled by the variety contained in this volume. It is occasionally clever, and one feels that the author is not without merit, but that is the best we can say of it.

PIPETTE MIDDLE-EAR SYRINGE.

By William S. Cheesman, M. D., AUBURN, N. Y.

Having experienced difficulty in using the ordinary ball syringe for washing out the middle ear through perforations of the membrana tympani, I recently sought some smaller and less cumbersome instrument. The elongated glass pipette suggested and used by Buck seemed very good, except for its stiffness and fragility, both dangerous qualities. It occurred to me that the lightness and handiness of Buck's syringe could be realized in a hard rubber instrument, with an ordinary pipette bulb and a fine flexible rubber tip, curved slightly at the end for ready introduction into perforations. This has been made very beautifully by Tiemann & Co., as shown in the illustration. I have taken great satisfaction in the use of the instrument, and feel no hesitation in recommending it to those who need a light, small, safe middle-ear syringe.

---

Miscellany.

ESMARCH'S HEMOSTATIC BANDAGE.—At a subsequent meeting of the same society, Dr. John H. Brinton said: "The few remarks I have to make on the subject do not rise to the dignity of a paper; I simply wish to bring to the consideration of the academy some objections to, or dangers from, the use of Esmarch's bandage as a constricting and controlling band. I have used the elastic bandage for many years, and I have had several cases in which the results were not altogether satisfactory.

"For instance, a number of years ago I operated at my clinic upon a woman who suffered from some serious bone disease of her leg. The Esmarch bandage was applied from the foot to the lower thigh, and the constricting band (the India-rubber tubing first in vogue) was placed just above the knee by a skilful hospital colleague, now deceased. There was no bleeding during the operation. The bandage had been applied and the operation was begun with the leg semiflexed upon the thigh, but during the operation the limb was extended. After the operation was finished I found that the constricting band had deeply divided the muscular tissues, posteriorly, almost to the bone. The large vessels and nerves were not injured. This damage resulted, not from the direct constricting force or pressure, but from the tearing of the tissues, firmly fixed above, by the extension of the leg during the operation. I was much annoyed by the accident, and dreaded the results. The patient, however, made a very good recovery; but the incident made a deep impression upon my mind.

"In this connection, I ask if any injurious effects of a similar kind have ever been noticed by the fellows of the academy from the movement of the limb after the constricting band had been applied. Of course, we all know that the first roller should not be applied too tightly over an ulcerating surface or a tumor, for fear of driving morbid material from the affected spot into the general circulation. There is another point about which I would like to ask the experience of the academy. It is in relation to the Esmarch bandage and secondary hemorrhage. A few weeks ago I made use of the Esmarch on a case of amputation at the knee joint. This is an amputation that I had done many times during our late war, and had then often noticed a tendency to consecutive secondary hemorrhage. In the two cases upon whom I did this amputation about a month ago I found a troublesome hemorrhage coming on about six hours afterward. I operated about two o'clock and was called about eight o'clock on account of bleeding. It was not in either case a free hemorrhage, but rather a persistent oozing from tissues which did not bleed at the time of operation. It came from the superior articular branches, and not from the axygos or inferior articular vessels, as the popliteal artery had been divided on the line of the articulation above their usual origin. I was obliged to open the stump and apply eight or ten ligatures to arrest the hemorrhage. I am unable to tell whether this hemorrhage was produced indirectly by the rubber constricting band or whether it resulted from some peculiarity of the case. It is possible that the band may have exerted undue pressure on the smaller vessels, producing vasomotor paresis, impairing their contractile power, and so have favored a post-operative enlargement, and a consequent reactionary or consecutive bleeding.

"In our old war times I have participated in many amputations at the knee, and I am certain that I have often noticed this tendency to consecutive hemorrhage. My object in bringing up this subject was to ask if any fellow of the academy has at any time observed any evil effects from the constricting band of the Esmarch apparatus, and also whether secondary hemorrhage may not be the result of its use."

In the discussion Dr. E. R. Wharton said: "I would ask if Dr. Brinton has noticed any difference as regards hemorrhage when the roller is applied first and the constricting band second and when the constricting band is used alone?"

Dr. Brinton said: "I have always used the first method, and can not, therefore, answer from my own experience."

Dr. Wharton said: "I think that there is always more hemorrhage after applying the elastic bandage, followed by the elastic strap, than by simply applying the strap. I think that there is a likelihood that the band is applied too tightly in many instances. The secret is in applying it with just sufficient force to do no damage, and simply to temporarily control the circulation. I have seen no cases injured by the use of the Esmarch tube or strap, but think its use is likely to produce more consecutive hemorrhage. Owing to a death from consecutive hemorrhage after the use of the Esmarch bandage a number of years ago, we have not, at the Children's Hospital, for many years used the Esmarch bandage or strap in cases of excision of the knee joint. The most satisfactory use of the
Esmerich bandage is for operations upon bone, for necrosis or caries. Another use for the Esmerich is in searching for foreign bodies, such as needles, etc., in the tissues; the search can be made with so much more comfort and with a greater chance of finding the foreign body if we first apply the Esmerich bandage and render the parts perfectly bloodless.

Dr. W. Bartin Hopkins said: "I can fully corroborate the statement regarding the risk of applying the circular turns of Esmerich too tightly, as I have for several years been in the habit of demonstrating the immense constricting force which these turns are capable of exerting. By drawing each turn with the utmost tension around a bit of white pine wood a decided crease may be made in it, fully demonstrating its power and giving an object lesson which is not easily forgotten."

Dr. Joseph I.earn said: "The Esmerich is generally applied too tightly. It is not necessary to use so much force. I can make a part bloodless simply by the application of my hand. My experience has been limited with secondary haemorrhage, as I have had no secondary haemorrhage. I apply the Esmerich very lightly, and always apply it myself. I only apply ligatures to the larger vessels, and have never had occasion to open a stump for secondary haemorrhage."

Dr. Barton said: "I have nothing to add to what has been said, except that in cases of resection for unfractured fracture I have found the Esmerich bandage unsuited, on account of the large amount of blood thrown out afterward. In operating for unfractured fracture of the humerus I would not use the Esmerich bandage, as I have had to remove the permanent plaster dressings for this cause."

Dr. Meaw said: "I was so much impressed with the harmful effects of the tube of the Esmerich apparatus that I substituted for it a flat rubber band, and reported its use in two operations in the Philadelphia Medical Times, August 15, 1874. I have seen a number of evil effects from the application of the tube, such as paralysis from pressure upon the nerves. I always use the band in preference to the tube, as being less injurious."

Dr. William II. Taylor said: "I have seen the Esmerich bandage applied too tightly, and have myself been very careful in this respect. In excision of the knee I have usually done without the roller bandage, and have used a wide band for the purpose of constriction. In all these cases there is a good deal of oozing, and after excision of the knee this oozing is decidedly increased by the use of the bandage."

Dr. Thomas S. K. Morton said: "With regard to the Esmerich roller bandage, I seldom use it any more for operations on the extremities, having had demonstrated to me in Glasgow by Mr. Macowan his method of making the limb bloodless. By elevating the limb for a few minutes we observe after a time that a spasm of the blood-vessels occurs and the limb becomes bloodless, and then the constricting band can be applied. With regard to the application of the bandage, I do not intrust this to an assistant, but always apply it myself. I always use the narrow strip and not the tube. I take this opportunity of saying that the Esmerich apparatus, as sent out by the instrument makers, is usually defective, because the bandage is too narrow; it should be wider. With regard to the paralysis following the application of the constricting band, it is most liable to occur when it is used just above the knee or elbow, and especially the latter, on account of the course of the musculo-spiral nerve. This occurs so frequently that we should prohibit the use of the Esmerich bandage around or above the joints."

Dr. Brinton said: "As a matter of historic record and justice, I wish to say in regard to Dr. Morton's description of the method of making a limb bloodless, as practiced by Macowan, that this method probably antedates the present day. I saw it practiced many years ago at the Jefferson College by the late Professor Joseph Pancost."

The President: "I also remember seeing Dr. Pancost applying a broad bandage to a limb in order to reduce the amount of blood in it, and take off the bandage before the operation. This was long before the Esmerich bandage was used."

Dr. Thomas S. K. Morton: "I think that I have been misunderstood. There was no bandage applied by Macowan; he simply elevated the limb and produced a contraction of the artioles, which made the limb bloodless before applying the bandage."

The President: "It is very remarkable in Dr. Brinton's case that the tissues were divided. Were the muscles cut or only the skin?"

Dr. Brinton: "The skin was torn slightly at one point and the muscles were distinctly cut through. I have not seen this accident mentioned in treatises on surgery, but in the American Text-book of Surgery it is stated that there should not be any motion of the limb after the band has been put on."

The President, Dr. Thomas G. Morton, said: "I have done very many operations upon the knee, but no amputations at the knee joint since the war. I have not, in many years, had any secondary haemorrhage."

Dr. Wharton added: "I have recently seen very little secondary haemorrhage. I had a case of reamputation of the leg last summer, where I had to apply the Esmerich bandage where consecutive haemorrhage occurred, and I had to open the stump and tie the vessels. I have not noticed any special liability to haemorrhage after operations at the knee joint."

The President asked: "In amputating at the knee, did Dr. Brinton remove the condyles or leave them?"

Dr. Brinton replied: "I referred rather loosely to these amputations as at the knee. In each case I saved off a portion of the condyles, if necessary to bring the flaps together, but there was not any haemorrhage from the bone."

The President asked: "What was the nature of the injury or disease?"

Dr. Brinton answered: "Both were cases of sarcoma."

Dr. T. S. K. Morton said: "Might not that have been the cause of the haemorrhage? I have noticed that in cases of operation for sarcoma there was much more tendency to bleeding than in ordinary amputations for injury. The vessels are often enlarged."

Dr. Brinton said: "The vessels did not appear enlarged."

Dr. Hopkins remarked: "I have not seen any haemorrhage, except after sloughing."

Dr. Hearne said: "I have not had any experience of this kind, and never have opened a stump for haemorrhage."

Dr. Brinton said: "I might say, to correct a possible misapprehension, that, although I have of late years done many amputations, these are the only two in which secondary haemorrhage has occurred."

The Nebraska State Medical Society.—The twenty-seventh annual meeting will be held at Grand Island, on May 21st, 22d, and 23d, under the presidency of Dr. J. H. Lowry, of Lincoln. The programme includes the following papers: Malarial Disease in Children, by Dr. W. F. Milroy, of Omaha; A Few Notes on La Grippe, by Dr. W. C. Robinson, of Clarke; The Small Intestine in Medicine, by Dr. J. S. Foote, of Omaha; Where are We At? by Dr. Charles Inches, of Scrivener; The Treatment of Diphtheria, by Dr. W. H. Christie, of Omaha; The Rational Drug Therapy of Typhoid Fever, based upon Bacteriological Investigation and the Observation of One Hundred and Sixty-seven Cases with Three Deaths, by Dr. O. Grothau,
of St. Paul; The Treatment of Typhoid Fever, by Dr. W. F. Milroy, of Omaha; Introduction to the Subject of Obstetrics, by Dr. J. Lu Sutherland, of Grand Island; The Evil Practices of the So-called Midwife, by Dr. Georgiana Grothan, of St. Paul; The Remote Effects of Abortion, by Dr. B. F. Crummer, of Omaha; The Survival of Superstition in Obstetrics, by Dr. H. Gibford, of Omaha; Traumatic and Chronic Irritations as Causative Factors of Tumors, by Dr. B. B. Davis, of Omaha; The Diagnosis of Diseases of the Stomach, by Dr. H. M. Exeret, of Lincoln; Tarsal Deformities in Congenital Talipes Equino-varus—the Wolff Method of Treatment in Selected Cases Illustrated, by Dr. W. Ross Martin, of Omaha; Aseptic Surgery in General Practice, with a Report of Selected Cases, by Dr. J. P. Lord, of Omaha; The Operative Treatment of Varicose Veins of the Legs, by Dr. J. E. Summers, Jr., of Omaha; Cholecystotomy, with a Report of Cases, by Dr. F. E. Coulter, of Omaha; When, Where, and How the Surgeon should Operate, by Dr. W. O. Henry, of Omaha; Ectopic Gestation, by Dr. A. F. Jonas, of Omaha; The Relation of the Medical Profession to our Hospitals, by Dr. B. F. Crummer, of Omaha; Ophthalmia Neonatorum, by Dr. M. H. Garten, of Lincoln; The Treatment of Perforating Wounds of the Eyes, by Dr. D. C. Bryant, of Omaha; Senate File 162, by Dr. J. V. Bechtol, of Friend; Catching Cold, by Dr. John W. Bullard, of Pawnee City; Empyema of the Maxillary Antrum, with Cases and their Treatment, by Dr. F. S. Owen, of Omaha; The Interdependence of Chronic Ear, Throat, and Nose Affections; their Clinical Histories, by Dr. George Wilkinson, of Omaha.

Football Injury of the Knee.—The Centralblatt fur Chirurgie for April 20th contains a summary of an article, published in the Hospitals-Tidende, by Dr. Mang, who is the physician to a school where the pupils are much given to football. He has observed a great number of quite similar lesions of the knee as the result of playing this game. The lesion consists of an inflammation of the patellar bursa. He ascribes it to the disproportion between the size and the weight of the ball, on the one hand, and, on the other hand, between the muscles and the tendons which set the ball in motion. The ball is moved by the vigorous contractions of the quadriceps femoris, which are spent on the ligamentum patellae. By the repeated occurrence of this action he thinks the bursitis is brought about. Dr. Rovsing, who made the abstract for the Centralblatt, thinks that the trouble is rather to be imputed to slight hemorrhages.

The American Gynecological Society.—The twelfth annual meeting will be held in Levering Hall, Johns Hopkins University, Baltimore, on May 28th, 29th, and 30th. The programme includes the following papers:

Recent Experience in Ureteral Work, by Dr. Howard A. Kelly, of Baltimore; Suprapubic Hysterectomy, by Dr. B. F. Baer, of Philadelphia; Hysterectomy for Uterine Fibroids, by Dr. S. C. Gordon, of Portland, Me.; The Use of Traction and Morcellation for the Removal of Fibroids, by Dr. T. Alldis Emmet; Ligation of the Pedicle with Catgut, by Dr. Archibald MacLaren, of St. Paul; Abdominal Section for Pelvisal Septicemia, by Dr. J. Montgomery Boldy, of Philadelphia; The Present Treatment of Uterine Displacements, by Dr. Paul F. Munson; Alexander’s Operation, by Dr. Clement Cleveland; My Experience with Ventro-fixation and Alexander’s Operation, by Dr. A. Lathorne Smith, of Montreal; the President’s Address; Renal Insufficiency in Gynecological Cases, by Dr. James H. Etheridge, of Chico; Total Expiration of the Uterus, by Dr. Charles Jacobs, of Brussels; Vaginal Hysterectomy for Conditions other than Suppurative and Malignant Disease, by Dr. Ernest W. Cushing, of Boston; Vaginal Hysterectomy for Uterine Myomata and Diseases of the Annexa, by Dr. William H. Wathen, of Louisville; Specimens Removed by Vaginal and Abdominal Hysterectomy, by Dr. R. Stansbury Sutton, of Pittsburgh; The Treatment of Uteroperitoneal Eclampsia, by Dr. Thaddeus A. Reany, of Cincinnati; The Prophylaxis and Treatment of Eclampsia, by Dr. Edward P. Davis, of Philadelphia; Deep Incision of the Parturient Cervix for Rapid Delivery, by Dr. J. Clifton Edgar; Trachoma of the Female Genito-urinary Tract, by Dr. Arthur W. Johnstone, of Cincinnati; Conservative Surgical Treatment of Septic Pelvic Disease, by Dr. Fernand Henrotin, of Chicago; The Ultimate Results of Tracheorrhaphy, by Dr. Willis E. Ford, of Utica; True Pelvic Celulitis, by Dr. Ely Van de Warker, of Syracuse; The Prevention of Uterine Disease due to Childbearing, by Dr. W. Giff Wylie; Decision of Maligmnz, by Dr. J. Whitridge Williams, of Baltimore; The Value of Gauche Drainage, by Dr. Henry C. Coe; Symphy-siotomy in Canada and the United States, by Dr. Robert P. Harris, of Philadelphia; Late Infection in the Puerperal State, by Dr. Egbert H. Grandin; Artificial Abortion, by Dr. Henry J. Garrigues; In Memoriam—Dr. William Goodell, by Dr. Barton C. Hirst, of Philadelphia.

The Use of Alcohol in Diseases of Children.—Dr. August Selbert, in an article on The Uses of Alcohol in Sick Children, published in the May number of the Archives of Pediatrics, considers first its application in the gastro-intestinal diseases. He makes the general statement that we can exclude all forms of gastro-intestinal disturbance in children from the list of diseases in which alcohol is beneficial. In acute cases, even in cholera infantum, large quantities of water with a small amount of black coffee or tea will stimulate better than alcohol. It is besides not irritating to the mucous membrane, already in a diseased condition. It is especially irrational and harmful to administer alcohol in the diarrheas of children before the stomach and bowels have been freed from all putrefying material. In typhoid fever he rarely gives alcohol to children or adults. In children the disease usually runs a mild course, and seldom relapses if proper diet is adhered to. Stimulation is rarely required.

In fibrinous pneumonia and broncho-pneumonia in children the author disapproves of the enormous quantities of alcohol which are frequently given. He does not use it in pneumonia, except when collapse threatens or is present. Then he uses it in large doses and in concentrated form. Alcohol-fed children will digest less perfectly in pneumonia than those whose stomachs have not been insulted in this way. Children who have received large amounts of alcohol do not regain their appetite and digestive power after the attack is over as those do who are treated without it.

In scarlatina alcohol is not tolerated by the stomach during the first few days. In severe cases the author has not seen any good results following its use. In mild cases it is out of place. The same is true of measles. In septic conditions during scarlet fever the judicious use of light wine sometimes seems to be beneficial.

In diphtheria the free use of alcohol has been universal. In mild cases the author does not administer it. Whenever the heart seems to fail he uses it in large doses, but only for a short time. As most cases of diphtheria are of mixed infections, it is proper to assume that the heart weakness may be caused by some of the other germs rather than by the specific bacillus. In emergencies he uses large doses, but for short periods. In nephritis alcohol in large doses can only do harm.

The Massachusetts Volunteer Militia.—The Boston Medical and Surgical Journal announces that Dr. Edward J. Forster, of Boston, has been appointed surgeon-general.
Lectures and Addresses.

THE WESLEY M. CARPENTER LECTURE.*

BY JOSEPH D. BRYANT, M.D.

PROLOGUE.

I DESIRE, Mr. President, before beginning, to state something of the reasons that actuated me in the selection of this subject for the evening’s consideration. While I know full well that I shall say nothing essentially new tonight, yet it occurred to me that perhaps it is not generally known that a steady increase of malignant disease is taking place in all civilized countries, notwithstanding the opposition of modern methods of treatment. In view of this fact it also seemed to me both proper and urgent that I should emphasize the necessity of greater efforts on the part of all concerned to resist this advance. The increased surveillance that is now being employed to defeat the attacks of the more common forms of disease is yielding rewards highly eulogizable to the forethought and assiduity of the profession. Therefore, may not increased effort, based on logical methods, do something to lessen the gravity of malignant infirmit?

It is proper too, at this time, that I express my grateful appreciation to those of my friends who have aided me in this endeavor. I mention especially Dr. Roger S. Tracy, of the Health Department of this city, whose knowledge of vital statistics is equaled by a few, and exceeded by none. Dr. George B. Stewart gave me untiring and intelligent support. Dr. Erdmann, Dr. Titterington, and Dr. Doty also contributed ably to the efforts of the others. It is to be regretted that the time at hand did not permit me to overcome the obstacles that were interposed between the anticipated results and the products of the endeavor. I wish through you, sir, to thank the Council of the Academy for the honor conferred on me, and for the expression of confidence which the selection implied, and finally, I hope that any feeling of disappointment that may come to-night as the result of the selection, will be tempered by mercy and charity for the speaker.

IMPORTANT FACTS RELATIVE TO MALIGNANT DISEASE.

The subject of malignant disease is not a new one. The warp and woof of its texture have been spun again and again. Various figures of thought, shades of opinion, with bright perspective, all tinted with hope, have been woven in the fabric only to fade away, giving place to others of a newer pattern, of fresher tints, better symmetry, and, perhaps, of greater endurance. The spinning still goes on, supported by increased opportunity, encouraged by extended experience, and stimulated by the hope of relieving humanity of one of the most inexpressible and cruel tyrants in the list of human afflictions. The encroachments of the common foes of human desire stimulate opposition and multiply the number and force of the ex-

* Delivered before the New York Academy of Medicine, November 15, 1894.

pedients best intended to resist invasion. The commendable and selfish efforts of those of great power, of unlimited means, and of extended influence are often made irresistible by the forethought, wisdom, and assiduity exercised for their advancement. Those of the human family who are thus circumstanced achieve great results for good and evil, and the opposition which they encounter, while it stimulates the utmost endeavor, nevertheless leaves the result, and the best is thus secured. Men strive for wealth and power that they may gain those things which wealth and power command: the pleasures and comforts of life; the high station in affairs that begets the confidence, respect, and love of fellow men. Men struggle for health and life for the personal comforts and possibilities that they proffer, and to defer that presence which all dread and yet none escape. Man’s battle for wealth, power, and fame is largely an individual one, for which he alone has made the attainment possible. Still, the influences that surround him, the interests that support him, and the principles that claim him, lead directly to the consummation.

Man’s battle for health and life is principally a subsidiary one; and the conflict is hardly more than a skirmish on his own part, until he fears defeat. Then he calls a council of war and abides the decision. Thenceforth he is a passive agent, endowed with a responsive intelligence which invites the fullest consideration of his council—the medical advisers.

Whether or not those who are inherently charged with the custody of man’s health exercise the same untiring scrutiny and indefatigable vigilance in his physical interest that he himself puts forth to secure pecuniary, official, or social advancement is a question of grave significance, whose answer should not be estimated except on the basis of recorded facts relating to disease. That an increased and concerted effort on the part of the medical profession directed against the hastening pace of malignant invasion is most urgent, is emphasized by the fact that this form of disease is increasing gradually and surely in nearly all civilized countries.

Whether this increase be an apparent one, due alone to the better means of diagnosis, or whether it be an assured one dependent on the influences of civilization, it is difficult to determine. At all events, it matters but little indeed for our present purposes which of these factors is the dominant one, since, that malignant disease is present and must be fought with the resources now at our command is self-apparent to all. Let us hope that a better knowledge of these circumstances will augment the vigilance of the physician in the same degree that it stimulates the aggressiveness of the surgeon. Already the period of post-operation immunity is increased, dependent, no doubt, on the closer observance of disease manifestations and a prompter and more thorough application of the recognized means of relief.

In war, as in well-studied contests for attainment in every other avenue of human activity, the attacking force considers the necessities that justify the combat; then determines the logical lines of the enemy’s advance, and final-
ly estimates the sacrifices of defeat and the costs of the struggle before engaging in the conflict. Permit me now to enlist your attention and support in the battle against malignant disease through the same line of action as that which characterizes human conflicts often of the basest nature.

The necessities that justify the combat relate to the loss of human life from the disease and the consequent sorrow and suffering dependent on the sacrifice. Each year the admonitions to duty are repeated with ever-increasing emphasis by the augmenting death record due to malignancy, as revealed by the vital statistics of this and other countries. Permit me to invite your attention for a moment to the established verdict of these statistics.

One has but to glance at the mortality tables here presented to be convinced that malignant disease exacts each year of the strength, comfort, and peace of a commonwealth a constant and liberal toll; and when it is remembered that this ever-increasing demand is inexorable in the procurement, notwithstanding the fact of the interposition of modernized methods of opposition, then indeed it behooves all, lay and professional alike, to unite in a tireless and vigilant crusade against a common, subtle, merciless foe.

In 1889 England lost 18,654 of her people from cancer (No. 1), this number being 3/6 per cent. of the entire death-rate for the year, giving an increase of two per cent. since 1865. A more careful estimate shows that the mortality there of the last ten years exceeds that of the preceding ten by 0.85 per cent., which is surely a decided advance.

In 1893 London alone lost 3,412 of her population from cancer, this being a percentage of 37/3 of the total deaths for that year (No. 2). This is the highest death-rate from cancer there since 1889; then it was 3.92 per cent., a difference of two per cent. between this date and 1869. The percentage of the last ten years is 3.51, that of the preceding ten years 2.67, giving an increase in favor of the latter period of 0.87 per cent. It is interesting to note the fact that the death-rate from cancer of England and Wales, exclusive of London, in 1892 was 3.62 per cent. of the total death-rate or 0.67 to the thousand living (No. 3). The detailed statistics of Scotland in 1888 (No. 3) bearing on the deaths from cancer show that in the smaller towns the death-rate from cancer to a "thousand living" is less than in the larger ones, and that in some cities and towns the rate is largely in excess of the rates of neighboring cities and towns.

The annual report of the registrar general of England for 1889 (pp. 13 to 18) contains a discussion on the apparent increase of cancer, from which the following extracts are taken:

"The deaths ascribed to cancer—using that term as a general designation for all malignant new growths—show a further increase upon the ever-growing rates previously recorded. Some of this increase is most certainly attributable to increased accuracy in statement of cause, and to the system introduced some years back of writing for further information in cases where some vague cause, such as 'tumor,' has been given as the cause of death in the original certificate. Nevertheless, in face of the constant and great growth of mortality under this heading, and the expressed belief of medical practitioners specially engaged in dealing with this class of diseases that they are really becoming more and more common, it seems scarcely possible to maintain the optimistic view that the whole of the apparent increase can be thus explained; and it must be admitted, as at any rate highly probable, that a real increase is taking place in the frequency of these malignant affections."

If we examine the cancer statistics of Italy for the year 1889 it will be found that in the less populous portions of this country the death-rate from cancer is less per "thousand living" than in the more populous provinces (No. 4). In the city of Berlin, in 1892, "cancer and tumors" claimed 1,138 of the people, which is 3.48 per cent. of the total deaths of that year. This percentage is the highest ever recorded there from "cancer and tumors." In 1877 a percentage of 2.10 is noted, giving an apparent increase of 2.38 per cent. in fifteen years. The comparative increase by ten-year periods can not be estimated, owing to the incompleteness of the records (No. 5). In 1890, 1,009 persons died of cancer in Vienna. This number constituted 4.96 per cent. of her total death-rate for that year. The last half of the sixteen years ending with 1890 shows an increase in the death-rate for cancer of 0.84 per cent. over the first half of the same period (No. 5). In Paris (No. 6), in 1893, 4.61 per cent. of the total deaths were due to cancer. In Munich (No. 6), in 1892, 3.98 per cent., and in Hamburg, in 1889, 3.78 per cent. of the total deaths were caused by cancer (No. 6). While the percentage is larger in the last three cities, yet no decided change for the worse is noticeable. Permit me now to direct your attention to those cities with which we are all in touch, and therefore we feel for them a personal as well as professional concern. The average death-rate from cancer in New York city during the last ten years is 2.17 per cent. of the total mortality (No. 7), but that of the preceding ten years only 1.82 per cent. Surely these figures are indicative of an increasing mortality from cancer. In the last twenty years, 14,309 persons have perished from cancer here, an average of about 718 per annum. It is important to notice that the death-rate from cancer in the State of New York in the years 1885, 1886, and 1887 was 2.37 per cent. of the total death-rate of those periods, and that this rate is 0.20 per cent. greater than the average death-rate of the city of New York during the last decade. This appears to indicate that the death-rate from cancer in the State at large is greater than in the city. According to a computation made by the late Dr. Carroll, of this city, it appears that the death-rate from cancer in the maritime portions of the State is much less than anywhere else within its limits, and that the greatest death-rate from cancer in the State is in the southern tier of counties. However, if a closer study of these figures be made, and the estimates be based on the death-rate from cancer to the "thousand living," then the strange results of Dr. Carroll's estimates are supplanted by a comparative death-rate in those sections of the State that is in entire conformity with such death-rates elsewhere in

* Transactions of the New York State Medical Association.
the world (No. 9)—that is, greater in the city than in the country districts. In Philadelphia the average death-rate of cancer for the last ten years is 2'24 per cent. of the total mortality, while that of the preceding ten years is 2'28 per cent. (vide No. 7). These figures appear to indicate a decrease in the frequency of deaths from cancer, were it not for the fact that during a year of the first ten years (1883) the death-rate showed the enormous and strange increase to 3'90 per cent., or nearly 1'5 per cent. above that of any recorded year of that city. However, in 1890 the recorded rate of death from cancer fell to 0'99 per cent. This rate, too, is likewise extraordinary, since it equals only half the percentage of death from cancer in 1876, which year had the smallest rate but one (1875) of the entire twenty years. It seems, therefore, not unfair to exclude these illogical percentages and base the estimate on those of the remaining eighteen years. If this be done, then an increase of 0'26 per cent. during the last nine years is apparent. I will not weary you with further detail, but will state briefly that the record of the last ten years reveals an increase from cancer greater than those of the preceding ten years of 0'54 per cent. in Boston (No. 8), 0'64 per cent. in Baltimore, 0'52 per cent. in New Orleans (No. 11), and 0'84 per cent. in San Francisco (No. 11). These examples are, in my judgment, quite sufficient to establish the fact of the gradual increase of the death-rate from cancer in these localities. It will be noticed that many of the preceding computations are based on the relation of the death-rate from cancer to the total death-rate of each city and country considered. This method gives less accurate results than estimates based on the percentage of deaths from cancer to the "thousand living," owing to the influence on the cancer percentage of the variations in the death-rate due to other causes. However, the uniformity of the death-rate from other causes in the majority of the preceding illustrations does not cause a material change in the result when compared with the latter method of computation. Other cities were asked for records bearing on the question, but as yet they have failed to respond.

The following table is very instructive as bearing on the increase of cancer in the United States:

<table>

In a private communication, Dr. Billings says, in connection with the record of 1890: "Permit me to call your attention to the fact that for the greater part of the United States the returns of deaths were very incomplete, there being no registration laws. The true death-rate was probably 18 per 1,000, and the death-rate from cancer and tumor per 100,000 living was undoubtedly greater than that above stated" (33:5).

If the attempt be made to compare the death-rate of large cities from this disease with that of the remaining parts of the country, remarkable results are attained. For in fifty large cities 39'94 died from cancer to the 100,000 living; while in the remainder of the country the death-rate from the same cause was 25'60 to the 100,000 living; showing the startling difference between the two of 16'34 to the 100,000 living.

On the other hand, if the percentage of deaths from cancer be compared with deaths from all known causes in both city and country districts, then especially a lowering of the death-rate from cancer in the city is seen, dependent on the large infant mortality from other causes.

If a comparison be made of urban with rural population at the periods of life when cancer is most prevalent, the excess then found is still on the side of the city. This difference is usually too wide to be accounted for entirely by the death-rate in the city of the non-resident afflicted who have sought relief by treatment there. It is, no doubt, true that much of the difference in the death-rates from cancer noted in city and rural populations is dependent on the deaths of the non-residents, who seek individual and hospital aid for the cure of their affliction. This fact is especially noticeable on the continent. In Berlin, from 1883 to 1888, the increase of non-residents in the hospitals of those afflicted with malignant disease was about forty-four per cent. From an official report of Breslau, 1889 to 1892, the following instructive extract is taken:

"The deaths from malignant tumors, which amounted to 14.9 per 1,000 of all deaths in 1877, but gradually increased to 25.4 per 1,000 in 1883, and 32.1 per 1,000 in 1891, shows clearly the effect upon the local death-rates caused by non-residents, whose proportion of the total deaths of this class was 8.3 per cent. in 1886, 9.8 per cent. in 1887, 11.8 in 1888, 14.4 in 1889, 13.0 in 1890, and 13.2 per cent. in 1891."

It is especially interesting to note the fact that in some portions of the United States cancer is apparently much more prevalent with the rural than the associated urban population; as, for instance, on the north Atlantic coast the rural district shows 31'42 and the urban 22.46 deaths from cancer in 1,000 deaths from all other causes. The middle Atlantic coast gives 20.25 rural to 19.93 of the city; northeastern hills, 33.23 rural to 17.53 of the city (Worcester and Hartford); south Atlantic coast gives 15.94 rural to 5.70 of the city (Charleston) deaths from cancer to 1,000 from all other causes.

The greater completeness of the mortality records of cities as compared with rural districts accounts for much of the difference in mortality rates from cancer, especially in Charleston, where the number of deaths from infantile diseases in the colored people is very pronounced.

Had these deaths been caused by cholera, or arisen from any other form of human affliction which threatened the safety of the people, or disturbed the avenues of trade, or impaired the haunts of pleasure, then, indeed, the aggressive resources of the country would have opposed their presence and perpetuation. If the same number of persons were to die annually in these countries as the result of open acute infraction of common law, a knowledge of the fact would furnish texts for innumerable advocates of human
redemption, and the basis of princely subscriptions in support of social reform. And, finally, if, despite these measures to establish reform, increased lawlessness were the only response to persistent effort for good, then tender consideration and mercy would be supplanted by vigorous prosecution and punishment.

As a further justification of the combat one need hardly stop now to estimate the importance of the pity of the stranger, the sorrow of the friend, or the anguish of the much-loved in this connection, since these emotions are a part of the life history of all who are endowed with healthy human sentiment.

The logical lines of this unthinking enemy's advance, in a comparative sense, differ in no essential respect from those long since established by the thoughtful study of opposing human agents in their assaults on each other. The vulnerable points are always assailed in human conflicts, and usually they are those of the freest communication.

The lymphatics, lymph nodes, and blood-vessels that are associated immediately with the disease afford easy exit from it of the malign influences that propagate and spread the infection. The malignant products of the original site find free access to contiguous lymph glands through the efferent lymph vessels of a diseased part. The onward march is halted there for a longer or shorter period, long enough at all events to plant the seeds of disease in the gland, which in turn sends on through similar channels to more distant glands its infecting products, and this repeated soon leads to wide infection, to constitutional involvement, and death. It is through these open and easily irrigable channels that malignant influences escape primarily and principally, as from a single spring, and with an ever-broadening and contaminating stream infect finally the entire sea of vitalizing fluid.

As proof of the part played by lymphatics in disease-spread I will call your attention to the results of the analysis of 100 non-hospital cases bearing on this point. In 09 of these cases enlargement of the associated lymphatic glands was present at the time of the primary operation. In 16 cases it is not stated whether they were present or not. In 15 cases only they were not detected by examination. This fact, however, is no proof that they were unaffected, since we frequently find on operation diseased glands infected by contiguous malignant growths that were too small to be appreciated before operation, and in some instances after removal they appeared but slightly enlarged, even though they were then pregnant with active malignant processes. In 94 cases of primary cancer of the tongue the glands were enlarged in eighty-three per cent. of the number. In 34 recurrent cases of this organ glandular enlargement was present in eighty-five per cent. In 118 cases of primary cancer of the breast the axillary glands were obviously enlarged in seventy-three per cent. of the number. In 42 recurrent cases of the breast the glands were enlarged in eighty-three per cent. of the total number. In 110 instances of non-ulcerated cancer of the breast the axillary glands were enlarged in eighty-three per cent. of the number, while in 50 ulcerated cases these glands were enlarged in ninety-six per cent. of the instances. Surely the inferences to be drawn from these examples bearing on the importance of early and thorough action are too obvious to require comment. One who omits the removal of lymphatic glands as a supplementary step to the excision of malignant disease should present a much better reason for the omission than that no appreciable enlargement of them was noticeable. The rapidity of the flow, the functional activity of the parts, the degree of the infectiousness of the fluid, and the susceptibility of the tissues to its influence, each in some part, or all combined, modify malignant disease dissemination. The blood-vessels, too, act as carriers of infection to every part of the body. Exactly at what period of the early history of a growth the lymphatics and blood-vessels begin the conveyance research has not yet determined.

A careful examination of the hundred cases discloses great paucity of statement regarding the time of the first appearance of enlarged glands, since in four cases only is this feature of development distinctly stated. In these cases two and five months were the extremes.

However, that the lymphatics and blood-vessels are the primary and principal agents of the dissemination of misfortune in malignant disease, and that their contributions to continued infection should be anticipated by an early, diligent, and wise interrogation of tissues possessed of special vulnerability, can not be controverted.

The points of least resistance relate to the immediate environments of the growth. The lymphatic network of vessels whose meshes embrace the tissues on all sides of the growth await with open mouths the opportunity to swallow the local infection. It is then carried by them principally in the direction of the lymph current to direct and more distant places, often poisoning the tissues as it goes along. It is important to remember, if only for conservative purposes, that the infection of tissues against the flow of the lymph current is of a limited degree and of sluggish attainment, while, per contra, active local and general infection attends the ebb tide of lymph flow in all parts of the body. Dense tissues with feeble blood supply are comparatively strong defensive barriers against the local assaults of this disease in its onward march of invasion. Loose tissue, abounding in cells and well irrigated with blood, offers an alluring point of attack for malignant invasion, and affords it a fertile field for triumph in the conflict with every natural and artificial reparative agency that opposes its course. The behavior of the resisting and opposing cellular forces in the advance line of conflict is conjectural in a large degree. But of two facts there can be no doubt:

1. That each peculiar cell opposes the advance of its antagonist with a cell vigor suggestive of cell duty and self-preservation. 2. That the healthy cell structures are pushed to the wall, as it were—literally overridden by the rapid advance of the innumerable venom-laden ones bred by the disease—is quite as clearly apparent to the uneducated eye of the layman as to the trained view of the physician.

The sacrifices of defeat, when one is opposed by an obdurate foe, should be sweetened always by the knowledge
that one's best has been done. Complete general victory can never be attained in a contest like this, since the ills of the flesh are the heritage of man. But much more will be gained, for years of profit, comfort, and pleasure will come; then the sense of duty better performed will soothe the sorrows of defeat.

The costs of the struggle comprehend great forethought during two or more periods of the conflict—the primary period, the secondary period, etc. To the primary period belong the early detection of the growth; the prompt acknowledgment of its presence; a prompt diagnosis; a prompt and thorough removal of all malignant manifestations. Early detection of a local morbid growth is a matter that relates almost unreservedly to the patient; he should promptly acknowledge its presence to a physician, who should institute at once prompt measures for an accurate diagnosis, and a prompt and thorough removal of all local disease revelations. Unfortunately for the victim, this series of promptness is rarely evinced. The histories of cases of malignant disease are not bristling with statements that the patients themselves have contributed much at the outset to a knowledge of the presence of a morbid growth, even though they had long recognized the fact that "something wrong" had appeared. Indifference, trepidation, and procrastination are the order of the day, and their benumbing influence on resolution and action have wrecked too frequently the otherwise well-anchored hopes of patients and friends. The indifference is often the result of the belief that nothing of such a nature can "happen to me"—an expression suggestive of the fact that the person regards himself as one more favored by fortune than is his fellow man. Such a belief as this is a selfish faith that often robs one of the gain which follows an earnest, consistent human endeavor. Trepidation leads to incomplete performance of duty, and therefore to the adoption of incomplete methods of preventive procedure. Procrastination cuts off until to-morrow the good and the bad alike; both are twin contributores to inaction and adversity.

Perhaps the patient attaches no importance to the growth, or fails to acknowledge its presence for dread of the truth or the folly of vanity. If the physician be told of the unwelcome visitor, he, too, from ignorance, inattention, or sentiment, may dismiss the matter lightly for a while, saying, "Come again in a month or so, and then we'll see." Yet, if he be wise and appreciative of the fact that all tumors are robbers, and, like their kind, may soon destroy the sources of their own enrichment, a prompt removal will quickly follow a prompt, accurate diagnosis.

As bearing on these items, let us examine for a moment the early histories of the hundred cases gleaned from other than hospital sources. It seems to me that such cases as these will illustrate the general trend of thought and action in dealing with malignant growths better than will cases taken from hospital records alone. The extent of the disease at the time of the first recorded professional observation will, I think, constitute one of the proper indices of the degree of promptness exercised in the case. The series of cases here quoted relate to the tongue and contiguous tissues, and are therefore more important than those of other regions of the body as bearing on the question of prompt action, because the exercise of the functions of these parts must have invited prompt recognition of the presence of a morbid process. Also, cases are selected from this series for the reason that the comparative increase of malignant disease is now greater here in the male than in other portions of the body. In the scheme of investigation, and under the heading "size, contiguous involvement, and situation of the tumor when first seen by the surgeon," appear the following startling examples descriptive of disease advancement: First case, "large prominence occupying great portion of the palate"; second case, "tumor size of bantam's egg"; third case, "large tumor extending into mouth across to right tonsil and causing fullness of the cheek"; fourth case, "extensive ulceration of tongue, floor of mouth, and alveolar process"; fifth case, "tumor size of orange depending from the soft palate"; sixth case, "tumor occupying posterior two fifths of the tongue." Now, when it is recalled that these six illustrations are found in the histories of eighteen consecutive cases taken indiscriminately from the series of one hundred, then, indeed, no stronger argument can be deduced to establish the fact that indifference, trepidation, or procrastination, one or all combined, contributed as much as did any other influence to the sad post-operative prognosis that characterized them. If a closer examination be made of the early history of cases bearing on the question of early recognition and prompt acknowledgment by the patients themselves, the following facts appear: First instance, "when first noticed, tumor size of a pea; thirteen years later, size of an orange." Second instance, when first seen, "size of a cherry"; when seen by the surgeon, "encroached on pillars of the fauces and dorsum of the tongue." Third instance, at first "size of a split pea"; later, "involved pillars of fauces and pharyngeal wall." These statements appear in the histories of twelve consecutive cases taken indiscriminately from the series. The following facts bearing on the time between the discovery of the growth and the period of primary operation are very instructive: First case: "Operated on eighteen years after the first appearance; then greater part of the superior maxilla was removed." Second case: "Operation five months after discovery; then portion of lower jaw, large portion of tongue, and floor of mouth excised." Third case: "Operation five years after first appearance; returned in three months." Fourth case: "Operation fifteen years after first appearance and one year after it was seen by physician." Fifth case: "Operation nine months after appearance; then tongue, hyoid bone, and epiglottis were removed." Sixth case: "Operation four years after discovery." These six examples of this phase of the subject appear in the histories of fifteen consecutive cases taken at random from the series of one hundred. In order that the hospital aspect of this part of the subject may be noted, I will call your attention to 119 primary cases of cancer of the breast taken from the Middlesex Hospital reports. In these cases it appears that an average of twenty-six months and a half had elapsed between the time the growth was
first noticed and the period of admission to the hospital. Twenty-eight of these cases were admitted within six months; 15, six to twelve months; 22, twelve to eighteen months; 13, twenty-four to thirty months; 4, thirty to thirty-six months; 10, thirty-six to forty-two months; 1, forty-two to eighty months; 3, forty-eight to fifty-four months; 3, fifty-four to sixty months; 3, sixty to sixty-six months; 4, seventy-two to seventy-eight months; 2, ninety to ninety-six months; 6, over one hundred and two months. In eighteen cases of primary cancer of the lip, taken from the same source, an average period of twenty-four months and a half had elapsed before the patient claimed admission to the hospital. Surely no one could wish for better evidence than the preceding to establish the conclusion that an era of education of patients, and perhaps of the people, is demanded in the interest of a prolonged longevity and cure of those afflicted with malignant disease. If to these conclusions, begotten of recorded facts, be now added the results of similar cases born of the easy recollection of most of the hearers tonight, then, surely, conclusive conviction of the urgent necessity of a campaign of education is doubly emphasized. And especially is this true since it further appears that the recorded cases are the product of the last decade.

A thorough, wide removal should always be practiced, and apparently sound tissue logically situated should be freely sacrificed to insure success.

That this proposition is correct, no one who regards malignant disease as local at the outset will have the hardihood to deny. But, even if this be not his belief, he can not fail to recognize the greater value of a healthy reparative post-operative wound, the offspring of a wise and bold removal, when compared with one laden with malignant products, the issue of narrow and timid action. It is difficult indeed to draw reliable conclusions from the results of promiscuous operations, because different operators form diverse estimates of similar cases. For this purpose a clinical or hospital series of cases treated by one who is known to practice bold and thorough methods should be employed. While invidious distinctions will form no part of this lecture, still candor compels me to say that the post-operative records of those surgeons who have the greatest reputation for extensive and wide operative methods disclose the best results in so far as disease recurrence is concerned. Secondary growths and glandular enlargements should be sought for in logical situations and be removed in a similar manner as their antecedents. These growths and enlargements are the vicious progeny of the original malignity, and should meet the same fate as that of their perversive progenitors. Timidity and incompetent examination foster incomplete removal; incomplete removal stimulates the activity of the growth and often too a distrust of the profession that causes the enrichment of quacks. Success at the outset means almost everything. Therefore the patient must be thoughtful and frank; the physician prompt and certain; the surgeon fearless and thorough, and all should then be vigilant, vigilant, vigilant.

The costs of the struggle of the secondary period contemplate the exercise of eternal vigilance, great patience, unselfish devotion, unfaltering determination, and often Christian fortitude on the part of all concerned. The unflagging employment of intelligent, patient, and periodic scrutiny of the suspected parts by the physician constitutes the vigilance essential for the detection of the earliest reappearance of malignant manifestations. The unselfish devotion of friends and attendants; the unfaltering determination of the surgeon to perform and of the patient to submit promptly to radical measures, require not infrequently the exercise of a degree of fortitude depicted by Milton when he wrote—

"Nor hate a jot of heart or hope;  
But will still bear up,  
And steer right onward."

And, too, one should not lose sight of the fact that a "faint heart" has the same relation to success with malignant disease that it has with the "fair lady."

The exercise of proper vigilance on the part of the sentinels who are engaged in every anticipated conflict is directed to the common points of renewed attack, and also to the period of expectancy and the aspect of the foe. The common points of renewed attack of malignant disease are at the seat of the primary operation, in the nearest associated lymph glands, and not infrequently the distant indirectly associated parts of the body. The seat of the primary operation is a common point of renewed attack, and the early and wide removal of malignant growths contributes more than any other one element to the failure of reappearance there. If the growth is removed early, it is then small, the infiltration is limited, and the lymphatics are less involved, and too, the resulting deformity is reduced to a minimum; each of which is an important desideratum. In 20 of the series of 100 cases of cancer of the mouth already quoted, the histories of recurrences are quite complete. Of this number 2 recurred at the seat of operation; 7 in glands contiguous to the seat of the primary disease; 8 appeared simultaneously at the seat of the operation and in the glands; in 3 instances the point of reappearance is not stated. In another series of 14 cases of recurrent cancer following primary disease of the tongue, 5 reappeared in the glands; 8 in the stump of the tongue, and 1 in both tissues simultaneously. Thus we have 34 recurrent cases, taken at large, in which the earliest physical manifestations of renewed malignancy should have been promptly detected by careful, continued, and logical scrutiny.

The period of expectancy is of very uncertain duration. In the 20 cases before alluded to, 5 reappeared in three months, 2 in two months, 1 in one, four, five, six, nine, sixteen, and twenty months respectively. One is reported to have returned "quickly," another in seven years. This, the last case, attacked the stomach and can not therefore be regarded as a recurrent one in the common usage of the term. In 3 cases the period of recurrence is not stated. One of the cases can not be called recurrent, since the diseased glands present at the primary operation had not
been removed, and soon thereafter became the seat of active malignant growth. The period of recurrence is modified in length by the situation, size, nature, and activity of the growth, etc., together with the promptness and thoroughness of removal. Inasmuch as a definite period of expectancy cannot be wisely fixed in any case of malignant disease, and therefore as the safety of the patient is secured only by continuous vigil, I will not needlessly encumber the lecture with records of periods easily obtained, and thus, perhaps, disarm wise discretion by the utterance of unreliable dogmatic expressions.

The face of the foe admits of no disguise, for even though it be masked by innocence, its past record of malevolence disarms the possibility of the escape of detection, even if only ordinary prudence be exercised.

In 1889, while considering this subject in a paper before the State Association, I made the following assertion: The surgeon's watchword ought to be: Cut early, cut often, cut wide, and remove contiguous lymphatic structures when practicable, whether diseased or not. This principle is much older than the expression. Later experience has in no way lessened the force of this statement in my judgment, but has, on the contrary, served to strengthen my belief in the wisdom of the course.

In nearing the termination of this lecture I desire to submit to your consideration the following conclusions:

1. That the death-rate of malignant disease is constantly increasing in all civilized countries.

2. That the death-rate is larger in cities, irrespective of the presence of the transient affected there, than in the country.

3. That in limited portions of the country, and in some cities, the death-rate from malignant disease is strangely and disproportionately large.

4. That this increase of malignant disease demands urgent consideration and prompt logical methods of combat on the part of all concerned.

5. That better post-operative prognosis can be attained by proper education of the afflicted and prompter action of the profession.

6. That when the considerations of health and strength shall excite the same degree of forethought and vigilance as the attainment of wealth and power does, then post-operative prognosis will be much improved.

But a few words more in the line of thought of the last conclusion and I am through. The strife for wealth and power on this little planet of ours develops keen and sanguine discernment, vigilant and tireless scrutiny, and sound, aggressive self-reliance, and the people are made better and their belongings more valuable as the result of a proper exercise of these endowments. Now, if it were possible that health be allied with wealth and strength with power in this battle of attainment, then indeed would Pope's sentiment—

"Reason's whole pleasure, all the joys of sense
Lie in three words—health, peace, and competence"

be realized.

**THE TREATMENT OF PNEUMONIA**, WITH SPECIAL REFERENCE TO THE VALUE OF HEAT.

By CHARLES WILSON INGRAHAM, M.D.,

BINGHAMTON, N.Y.

Called to treat an adult case of acute lobar pneumonia in its first stage, or stage of congestion, what means can we employ which shall have the effect to minimize danger and magnify the chances of recovery? What remedies administered internally; what substances or apparatus applied externally; what inhalations—gas, vapor, sprays, or other means whatsoever—are to day at the command of the general practitioner which will have the effect to modify symptoms, to reduce, avoid, or control the dangerous features of the disease, and to facilitate convalescence? Uncomplicated pneumonia is in a large percentage of cases a self-limited disease, and any treatment or method administered with a view to shorten its duration is fruitless and may even be harmful. After consolidation has occurred it is as impossible to abort pneumonia as to abort typhoid fever after the formation of Peyer's patches; and instead of loading down the system of the patient with depressing drugs, and depleting his vitality by drastic purgatives in vain efforts to accomplish this impossible feat, we should concentrate our efforts upon a definite line of treatment that has for its motive the achievement of three fundamental principles—namely, to support nutrition, and by so doing sustain strength, vitality, and resistance; to modify painful or distressing symptoms, and by so doing...
encourage mental and muscular rest; to relieve, uphold, and fortify the cardiac functions.

These three essential points kept constantly in mind and given careful, intelligent, and systematic attention, combat a multitude of more or less serious conditions and complications, which stand ever in readiness to break in upon the field and disorganize and confuse the whole outlook.

In order to more clearly present my subject and render a more intelligent conception of my theory, it will be necessary to draw a descriptive picture of a typical case of acute lobar pneumonia occurring in an adult, and color the same with the physiological and pathological demonstrations ordinarily associated with the disease.

Many practitioners are enabled to recognize a case of pneumonia at a first glance, because of certain visible changes or conditions. The dark, flushed hue of the face and temples; the general expression of anxiety; the panting, rapid breathing, which calls into play the extraordinary muscles of respiration, the sterno-mastoid muscles standing out prominently; the harsh cough—all contribute to the diagnosis of acute pneumonia, and the physician knows what he is going to hear before he puts his ear to the chest. These symptoms are external indications of the internal condition.

Put an animal under a bell glass and as the air becomes exhausted we see the typical symptoms present in pneumonia—the blueness of the skin, the rapid breathing bringing into play all the muscles of respiration, the anxious expression; in fact, everything but the cough.

The symptoms in either case depend upon a lack of oxygen and an excess of carbonic acid, and our most skillful efforts in the treatment of pneumonia should be directed to increase the amount of oxygen in the system, to eliminate the excess of carbonic acid, and to bring them as near as possible to their proportions in health.

With the onset of pneumonia, one or more lobes of the affected lung become consolidated and—like a depositor's money in an insolvent bank—the blood circulating through the affected portion of the lung at the inception of the disease becomes stagnated and coagulated, thus depriving the system of the quantity of blood that the pulmonary vessels of the involved area ordinarily contain. We know that more than double the amount of blood could be drawn from the system—following the onset of the disease—with little or no constitutional effects; without causing any depressing results or inducing any functional disturbance of any one of the various organs of the body. Indeed, the results might be favorable following such an operation. Therefore it is not the loss of blood that causes the intense depression of the vital forces following the onset of acute lobar pneumonia.

The lungs are composed of five lobes. Will the consolidation of one lobe and consequent total suspension of its functions so disorganize the equilibrium of the respiratory mechanism or so diminish the breathing surface of the pulmonary organ as to endanger the system from lack of oxygen, from inability to eliminate the poisonous products ordinarily thrown off by the lungs, or from any other pathological condition consequent upon impairment of the respiratory functions?

It is a very common occurrence to see a person afflicted with pulmonary phthisis—the extent of destruction of whose lungs more than aggregates one or even two complete lobes—in whom there are not present at any period of his disease any of the respiratory or cardiac symptoms present in acute pneumonia. Furthermore, such an individual might undergo a severe pulmonary hemorrhage from the effects of which he would lose a large quantity of blood, much more than could be imprisoned in the vessels of a consolidated lobe, and yet experience none of the phenomena associated with pneumonia.

It is thus easy to prove by analogy, by the comparison of two pathological conditions which sufficiently resemble one another to allow of the comparison, that it is not the restriction of pulmonary surface or loss of blood that occasions the typical symptoms of pneumonia, and that they contribute to the condition as a whole only to a limited extent.

Neither is the condition resultant of the initial chill, the pleurisy, the temperature, the systemic shock, nor any other symptoms typically associated with the inception of the disease.

We thus find, upon dissection of the visible symptoms and conditions, examined singly and collectively, no cause that would give rise to the effect.

Without knowing the actual working capacity of the veins, arteries, and capillaries of a healthy pulmonary lobe, let us assume, for example, that such a lobe has constantly under motion in its vessels one fortyth of the whole quantity of blood in the body.

In order to maintain the correct proportion of oxygen and carbonic acid in the tissues and fluids of the body, this lobe must oxidize and purify one fifth of the whole amount of blood in the system.

What effect upon the system, local and constitutional, will be the result of the consolidation of one lobe?

The superior and inferior vena cava steadily pour their flow into the right auricle, and the right ventricle is obliged to pump the full amount brought to it, through the diminished area of the pulmonary circulation.

In order to compensate for the loss of one fifth of the oxidizing surface and blood capacity, the veins, arteries, and capillaries of the uninvolved area are worked to their utmost capacity, and the blood tension in these vessels must be increased twenty per cent. above the normal, while the tension in the blood-vessels of the systemic circulation is nearly or quite normal.

Take, as an example, a system of rubber pipes supplying water to a large factory. Suppose that, by the maintenance of a pressure of fifty pounds to the square inch, a condition of perfect equilibrium is maintained—that is, the entire supply is exactly disposed of—the supply is precisely equal to the demand. An accident occurs to one portion of the piping representing one fifth of the capacity of the entire system, and the water is shut off from this damaged part, but it is impossible to diminish the amount of water supply or pressure. Therefore the re-
maining four fifths of the tubing must have its capacity increased in proportion to the extent of the damaged area. As water can not be compressed, the tubing must of necessity expand, and the pressure thrown back upon the boiler is in exact proportion to the amount of force required to sustain this expansion. More fuel is required to generate the required amount of force, and if the amount of force required is above the ordinary capacity of the boiler (as a diseased heart from organic or systemic cause), serious results may be expected to occur. It is principally a question of fuel; but the best of boilers can not support a tension twenty per cent, above their capacity for any lengthy period.

The situation would be rendered more dangerous if the piping from neglect or abuse has become hardened and can not yield or expand to accommodate the additional water pressure. Such a condition would be analogous to that found in the blood-vessels in the chronic inebriate, in the gouty, in the rheumatic; and in such cases the condition is more critical because the heart is usually below the normal standard.

This example, which gives a perfect picture of the condition of the heart and the circulation in monolobular pneumonia, shows us exactly what we must accomplish if we expect our treatment to increase the chances of recovery.

We must dilate, relax, or enlarge the blood-vessels of the healthy portion of the pulmonary organ, so that it will accommodate the extra twenty per cent. of blood which is required to circulate regularly through the lungs in order to maintain the equilibrium of the circulation, so as to supply the system with a sufficient amount of oxygen, and to relieve the system of the poisonous products of respiration.

But how are we to accomplish this and reduce the tension in the pulmonary vessels to a sufficient degree to appreciably relieve the heart?

The old-time practice of bleeding the patient accomplished this to a certain extent. By drawing blood from one of the extremities, the amount drawn was immediately replaced from the portion of the body where there was the greatest tension. It served to equalize the circulation and quiet the arterial excitement, and in plethoric patients it was attended with success to a certain extent; but, as only a small percentage of pneumonia patients were plethoric, the universal practice of bleeding did, on the average, more harm than good. The number of deaths caused by bleeding, without doubt, exceeded the number of lives saved. The result of bleeding has the undesirable effect of greatly diminishing the number of red blood-corpuscles, which should be increased rather than diminished.

This blood represented a certain amount of vitality and force, and was needed by the patient to carry him through the systemic exhaustion of the disease, and by depriving him of it, even though it for a short time effected a very desirable physiological result, his chances of recovery were diminished in proportion to the amount of blood withdrawn.

Veratrum viride lowers the blood pressure by its action upon the heart muscle and by its depression of the vasomotor center, and in the early stage of pneumonia will bring about the same physiological results that follow the operation of bleeding. "It bleeds the patient into his own blood-vessels." But, while it accomplishes temporarily certain desirable effects, its use is not to be thought of for a moment. It is worse than valueless.

There is but one remaining agent that will produce the desired effect, and that is heat, the king of all remedies as regards results, immediate and permanent. It is a powerful stimulant and antispasmodic, and the whole effect of heat properly applied reaches a higher degree of perfection in the treatment of acute pneumonia than is possible in any other pathological condition.

It relieves pleuritic pain. It induces copious but not exhaustive perspiration.

It is a reliable antipyretic if used in a way to obtain its full physiological effects at an early stage of the disease.

It controls the disease and prevents its further spread.

It is a powerful and reliable cardiac stimulant, a fact long recognized by the laity as well as the profession.

Its powerful antispasmodic effects have long been recognized in the treatment of dysmenorrhea, spasmodyc group, gastralgia, neuralgia, rheumatism; and its power of vascular relaxation is demonstrated in sprains, bruises, inflammatory rheumatism, etc.

In my experience heat, moist or dry, has proved most reliable and valuable, and, if I were obliged to choose between heat and all other remedies, internal or external, I should choose the former.

The great and only shadow which has enveloped this truly grand remedy has been the lack of an apparatus by the aid of which it can be applied to bring forth its full therapeutic effects. To properly apply heat in the treatment of pneumonia, a high temperature should be continuously and uninterruptedly maintained. The old-time poultice is possessed of so many disadvantages as to more than neutralize its good effects. Poultices are, as a rule, applied over the involved area with what expected ultimate effect I know not, but presumably to hasten resolution of the hepatized tissue and relieve pain. While it is possible that they may possess this power to a limited degree, I can not believe that the benefit actually obtained warrants the inconvenience and possible dangers, even when the process of poulticing is in the hands of careful and experienced nurses, as it is almost an impossibility to keep the body from being chilled more or less when the changes are made. The more experience I had with poultices in the treatment of pneumonia, the more convinced I became that the patient would recover fully as soon and with as much certainty when poultices were not used. The more I saw of the effect of heat as a therapeutic agent, the more I became impressed with the idea that if this agent could be utilized in a manner to obtain a maximum amount of its advantages, with a minimum amount of dangers and inconveniences attending its use, it would be one of the most valuable and reliable remedies at our command in the treatment of pneumonia as well as a multitude of other affections. I obtained the services of a skilled engineer and mechanic, and, pointing out to him the inadequate
means at the command of physicians and nurses to utilize heat, requested him to invent an apparatus which would overcome the obstacles with which we had to contend. He conceived the idea of utilizing known scientific principles and, with occasional advice from me, finally completed the construction of an apparatus. In two years' experience, during which time it has seen much service, the faults in its general workings have been corrected and improvements added so that it now approaches a degree of perfection not dreamed of when its structure was begun.

The apparatus on the whole is exceedingly simple and consists of an adjustable flannel jacket which covers the thorax anteriorly and posteriorly. To this jacket is attached rubber tubing, coiled and arranged about an inch apart, and attached to such an extent of the jacket as to completely envelop the sides and front of the thorax. The rubber tubing is skillfully mounted in such a manner as to prevent kinking at the curves, and the patient may lie upon it with perfect ease and comfort, and not interfere in the least with the working of the apparatus.

After the complete jacket is adjusted to the patient, a feed tube is attached to a small reservoir of hot water, the heat of which is maintained by a kerosene, alcohol, or gas burner. The reservoir is placed several feet higher than the patient, and the hot water circulates through the tubing and is finally conducted by a discharge tube to a vessel at the foot of the bed. A thermometer is placed in the supply tank and the heat kept at an exact temperature. As the water flows through the tubing it diffuses a gentle penetrating heat, and in its passage through the entire jacket only a slight cooling of the water takes place, for the thermometer will indicate only a few degrees lower at the discharge tube.

When the jacket is first applied the water should be allowed to flow under a full head for a few moments, following which it may be so checked as only to drop into the discharge tank. The flow of the water is controlled by stopcocks at the reservoir and at the end of the discharge tube.

The rubber tubing is so arranged that it can be removed from the jacket in order to facilitate the cleansing and disinfecting of the apparatus.

After treating a considerable number of cases of pneumonia as well as a variety of less dangerous acute diseases of the lungs, I have yet to see the patient who did not experience the most marked benefit from the effect of the apparatus.

Respiration became deeper, less laborious, and markedly reduced in rapidity. This effect is explained by the fact that a high degree of heat so generally applied as to act upon the entire surface of the respiratory organ, enlarges the caliber of the blood-vessels of the uninvolved portion, thus allowing of the reception at a normal tension of the blood which would in the healthy state go to the area now consolidated. This has the effect of relieving arterial tension, of exposing a greater surface or area of blood to the air-cells (by the increase in the capacity or caliber of the veins, arteries, and capillaries), thereby relieving the heart action and encouraging a normal interchange of oxygen and carbonic acid.

In a period of six hours, in cases of true lobar pneumonia, I have known respirations to diminish one third in number, accompanied with a corresponding diminution of temperature and pulse beat.

Recent experiments have proved that a high degree of heat continuously applied to the abdomen will have the effect of greatly increasing the capacity of the abdominal blood-vessels, and by virtue of this physiological effect it has been proposed to apply heat to this region of the body in the treatment of pneumonia, with the belief that it would relieve the arterial tension in the pulmonary circulation. But this method appears to me to have one serious drawback—namely, that the blood accumulated in the abdominal blood-vessels would not be sufficiently oxidized, and we would be working to our harm in thus favoring an accumulation of carbonic acid in the system.

By dilating the pulmonary blood-vessels to the extent of allowing them to easily compensate for the consolidated area, thereby receiving at the normal tension or pressure the venous blood as fast as it flows into the right heart from the systemic circulation, we are approaching the height of perfection in the treatment and management of pneumonia.

In cases where an abnormal amount of adipose tissue retards the action of the heat, an abdominal appliance has been arranged for attachment to the jacket. The abdominal appliance would also be indicated if the patient was a chronic inebriate or affected with any disease which would have been liable to have hardened the walls of the blood-vessels, allowing of only a limited relaxation.

The "pneumonia jacket" has the following principal advantages over the ordinary methods of applying heat to the chest:

1. The heat can be accurately regulated to suit the requirements of any case.
2. The heat can be continuously applied without disturbing or exposing the patient.
3. There is no dampness or chilliness, as is apt to be the case with other methods of applying heat. The moisture from the skin when the apparatus is being operated allows all the action of moist heat.
4. A continuous even temperature can be maintained indefinitely.
5. The different appliances are light and adjustable, are never out of repair, and are perfectly comfortable for the patient.
6. The working of the apparatus is entirely automatic and the labor in operating it is very slight. The work and anxiety of the nurses and attendants are reduced to a minimum, as the thermometer in the reservoir furnishes an accurate and reliable guide, while by other methods everything is uncertain and the temperature constantly varying.
7. The uninvolved as well as the involved area has the advantage of the heat with the splendid effects above detailed.
8. The patient need not be disturbed or the chest exposed during the entire course of the disease.

Having considered the effects of heat, the general management of the disease can now be considered.
In the treatment of pneumonia remedies may be administered by the following methods:

1. By the alimentary canal.
2. By hypodermic injection.
3. By inhalation.
4. By external application.

As early as possible a five-grain dose of calomel should be administered for the purpose of unloading the bowels, increasing the flow of gastric and intestinal fluids, stimulating the hepatic circulation, and thereby increasing the patient's powers of digestion and assimilation.

If pleuritic pains are intense an eighth of a grain of morphine sulphate should be administered hypodermically at once and the pain subsequently controlled by opium in one-grain doses, which not only controls pain but exerts a general stimulant effect upon the circulation.

The pain and irritable cough controlled by opium, no other remedy need be given internally unless called for to support the heart, with the only exception of perhaps controlling some simple functional disorder.

To sustain nutrition the nurse should be instructed to give the patient a glass of milk every hour, night and day. The form of milk should be occasionally changed, which will usually prevent the patient from rebelling against the method. Horlick's malted milk or Fairchild's peptonized milk powder may be alternated with ordinary milk. The former preparation is particularly nutritious and sustaining, and to the majority of sick people it presents a very pleasing and palatable beverage. There should be no laxity in the regulation of a "glassful every hour," and the rule should be carried out with as strict regularity as though we were giving the most important medicine, which it in reality is.

Beef foods in the form of "Wyeth's beef juice," "liquid beef peptonoids," or "beef juice extracted by means of a hand press" should be administered at regular intervals, so that the liquid equivalent of three pounds of beef is taken daily.

With this milk and beef diet systematically carried out we have the patient supplied with nourishment which will sustain a high degree of nerve and muscular strength sufficient to uphold a vigorous, comfortable, and unendangered heart action that should carry the patient through any ordinary attack, other conditions receiving equal attention.

It is not in the scope of this paper to discuss the many remedies designed to support the action of the heart. Medical literature on this subject is extensive and is accumulating daily. I will, however, state that I believe no cardiac stimulant should be administered until the same is plainly indicated. The stimulant treatment should be exclusively withheld until an embarrassed heart action demands the administration of the same, and it should then be given to the physiological limit. The successful general holds in reserve his heaviest guns, and at the proper moment concentrates their fire upon the enemy with uresisting vigor, and so with the physician; he ever holds in reserve, ready for instant use, the cardiac stimulant, and finally, at the critical period (should such a period occur), by administering the same to the full physiological limit or until the desired effect is produced, he remains master of the situation.

The question of inhalations is an important one, but may be disposed of in a very few words, for there is but one respirable agent that has stood the test of experience and proved to be of undoubted merit. This agent is oxygen gas, given absolutely pure or diluted with air. In my experience, pure oxygen gas given in quantities of from twenty to fifty gallons daily, beginning with the first inception of the disease, has demonstrated a physiological and chemical control over certain conditions of the system invariably associated with pneumonia. As the crisis approaches it should be administered more or less continuously, particularly if there is blueness of the lips and finger-nails, which indicate systemic poisoning from accumulations of carbonic acid. Oxygen gas is, however, a very much abused agent, as many physicians do not begin its use in a case of pneumonia until alarmed at the development of unfavorable symptoms. They then commence its administration; but in many instances the condition is so far advanced, the system is so saturated by the accumulation of the poisonous products of impaired respiration which have paralyzed and disorganized the nerve centers and thereby depressed the vital forces, that reaction would be impossible even though the entire aggregation of deleterious substances could be instantly withdrawn. The physician exposes his patient to unjustifiable danger in postponing to the extreme limit the administration of oxygen, and at the same time reflects unfavorable criticism upon a valuable and reliable therapeutic agent.

To reduce the temperature by the use of antipyretics is analogous to pouring water on the fuel of an overworked engine, and is to be condemned in unqualified terms. By the use of antipyretics in pneumonia we are working to our own defeat and to the destruction of the patient. We are antagonizing the efforts of Nature.

To shorten the duration of the disease and promote resolution should not be our object in view. If we properly treat the condition and maintain nutrition, avoid complications, support the vital organs, and sustain the natural resisting powers, the disease will retain the verdict of the majority of physicians and prove itself to be self-limited.

The following cases will serve to illustrate the promptness with which the rubber jacket transmits the effects of heat:

Miss B., aged twenty-four years. Symptoms: Contracted acute bronchitis in a severe form, which quickly developed into lobar pneumonia. Profuse expectoration of typical rusty sputum. Temperature when first seen, 103° F. Respiration, 35. Breathing much distressed. Patient's condition rendered more critical by the presence also of pulmonary tuberculosis in the first stage.

Oxygen gas was administered, but without appreciable effect. Six hours later (9 a.m.) a rubber jacket was applied and a high degree of heat maintained. Within an hour respirations diminished markedly in frequency. Breathing much relieved. The following day the temperature did not exceed 102° F. Expectoration free. Respiration nearly normal. The patient made a perfect recovery, and at no time was the heart embarrassed.
Miss C., aged eighteen years. Symptoms: Following exposure, suddenly developed acute pneumonia. When I first saw her the temperature was 104° F.; pulse, 120; respiration rapid; face flushed; breathing labored; expectoration typical. Severe pleuritic pain over the middle lobe of right lung. All efforts to relieve her condition proved unavailing, and two days later I applied the rubber jacket. Almost immediate relief followed. Respirations diminished in frequency. The heart became less embarrassed. A high degree of heat was maintained for several days, when resolution occurred and the patient made a good recovery.

Mr. A., aged thirty-five years. While suffering from an attack of la grippe was suddenly seized by a chill, followed with severe pain over the middle lobe of the right lung. Respiration at once became labored, and when I saw him several hours later temperature was 103-5° F.; respiration, 32; pulse, 110; face flushed.

Physical examination disclosed rough respiratory sounds localized to the middle lobe. No consolidation had yet occurred. Cough dry and exceedingly irritating.

Applied rubber jacket at once. A high degree of heat was maintained. The patient became much relieved from the first. The following day at noon the temperature was 99-5° F.; pulse, 100; respiration normal; cough loose; pain wholly relieved.

Second day, pulse 90; temperature normal.

The patient made an uninterrupted recovery.

**DIFFUSE EXTERNAL OTITIS FOLLLOWING THE CARELESS USE OF CARBOLIC ACID.**

By M. D. LEDERMAN, M. D.,

Lecturer on Diseases of the Nose and Throat, New York Polyclinic; Attending Aural Surgeon, University Medical College Dispensary; Assistant Surgeon to Manhattan Eye and Ear Hospital, etc.

Every now and then an individual who has followed the directions of a friend in an attempt to cure some ailment by home treatment appears before us as an animate illustration of a "horrible example." The case I herewith report is but another instance of this oft-repeated practice, but fortunately for my patient the result has been decidedly better than one would have anticipated from the appearance of the parts at the first examination.

It is a common practice among the laity to suggest domestic remedies for the relief of itching or painful ears. Among the remedial agents usually recommended may be mentioned candle or goose grease, sweet oil and laudanum, baked onions, spirits of camphor, and ammonia. These are but a few of the many irritants employed in the household medication of this sensitive and delicate organ. As medical science advances our fin-de-siecle laymen become more learnedly self-assertive and generously impart their limited knowledge more authoritatively. To this fact I am enabled to report the history of an unusual case.

Julia B., aged twenty-three years, married, presented herself at my clinic, Manhattan Eye and Ear Hospital, on Monday, December 17, 1894. She stated that for four years her ears had annoyed her at different periods by an intense itching sensation which extended into the external auditory canals. Up to within a few days of the above date she was in the habit of scratching the pruritic surface with the head of a pin. This procedure gave relief, but usually brought on a watery discharge, followed by the formation of crusts. When the symptoms returned she resorted to this palliative manipulation. No pus was ever observed coming from either ear, nor was pain experienced at any time. The patient's discomfort was, no doubt, due to the ordinary form of an antral eczema. Her hearing was always good.

On December 15, 1894, the itching resisted the usual treatment, and, following the advice of a friend, Mrs. B. poured some pure carbolic acid into a glass of water and syringed the mixture into both ears. The left ear causing the most distress, she subjected it to six applications of the remedy on Saturday and one on Sunday. But one injection was thrown into the right ear. When asked how much carbolic acid was used to each glassful of water, the young woman remarked that she had not measured the quantity, but thought that it would fill two teaspoons. Further inquiry elicited the information that the medicine was not mixed with the water, so that the acid floated on top, and with each initial injection pure carbolic acid was the remedy applied. Although this treatment was employed every two hours, by means of a small glass syringe, it is astonishing that no permanent impairment of hearing resulted.

Immediately after the first syringing the patient felt a tingling in her ears, but pain caused no discomfort until the evening of the first day (Saturday). During the night her rest was continually disturbed on account of its severity. Externally, the parts had swollen considerably, and were quite sensitive to pressure. The hearing now began to fail; those attending her had to speak in louder tones, otherwise their conversation was not audible.

**Sunday, December 16, 1894.—Mrs. B. could not hear at all with the left ear, but heard the voice through the right one. She noticed that during the day her urine was darker in color than normal. Macule volantes appeared and the vision was perceptibly affected. Poultices had been applied, and though the pain was somewhat alleviated, their application no doubt infected the excoriated surfaces, as the appearance of the tissues indicated when the case first came under my care.**

**17th.—Two days after the heroic treatment was the date of my first examination. Mrs. B.'s face presented a peculiar puffy aspect, due to a serious inflammation, which had evidently originated at the pinna, and had extended over the malar and external infraorbital regions. The conjunctiva of both eyes was much injected; diffuse swelling of the auricles existed to such a degree as to almost obliterate anatomical relations. On the left side it was especially prominent in front of the tragus, and could be distinctly outlined over the angle of the jaw. Pressure over the mastoid caused pitting, but no sensitive areas were discovered. With the exception of the mastoid and cervical edema, the same condition of affairs, somewhat modified, existed on the other side. Serum filled the fossae of the auricles and exuded from beneath a pseudo-membrane which covered the tragi, antitragi, and scaphoid fossae. Both external openings of the auditory canals were masked by the edema. An unpleasant odor emanated from the injured structures, and as the membranous deposit aroused suspicion a culture tube was inoculated. Testing with the tuning fork permitted the exclusion of internal ear disease. The watch could not be heard with either ear, but patient distinguished the voice when spoken to in loud tones. From the history of the case, together with the appearance of the parts, a diagnosis of traumatic diffuse external otitis was made, subject to the report of the bacteriological examination, which latter excluded any doubt. Bearing in mind the possibility of an atresia of the canal as a sequela, a guarded prognosis was given.**

**18th.—Much pain was experienced during the night, which was relieved by hourly doses of eodeine, an eighth of a grain. Owing to the sensitiveness of the canterized surfaces, the supine**
position had to be assumed during attempts at rest. Slighting was anticipated on account of the unhealthy appearance of the affected areas and the disagreeable odor which still persisted. Labarraque's solution as deodorizer was ordered. No further medication was deemed necessary.

21st.—Examination at this visit showed decided improvement. The swelling of the face and over the mastoid was almost gone. Sleep was not disturbed during the two nights passed, and pain only appeared when the parts were dressed. Furthermore, the offensive odor was not discernible. Both ears presented a more normal state, as the fossae with their boundaries could now be plainly seen, though some edema, with excoriations of the tragi and antitragi, still existed. Externally, on the left side, the orifice of the auditory meatus was distinguishable, but no view of the membrana tympani could be obtained, except for some swelling of the tragus, with denudation of the demodic coat, the auricle of the right side was in good condition. Even here the lumen of the meatus was still encroached upon by the infiltration, so that the membrana tympani could not be definitely outlined. H. D., L. E., W. 38; H. D., R. E., W. 38.

As matters were progressing favorably the chlorinated soda solution was continued. Saw patient every other day until December 31st. At these visits politerization was practiced. During the interim the edema gradually disappeared, so that the external structures had again assumed their usual proportions. Patches of desquamated epithelium were seen in the scaphoid fossae and canals. Both drums were now visible, thickened and retracted, with the cone of light shortened. Conversation carried on in ordinary tones was readily appreciated. H. D., L. E., W., 38; H. D., R. E., W., 38. An omentum of tar and oxide of zinc was prescribed for the pruritus, which again returned. Arsenic and iron were given internally. Inflation of the middle ear was continued regularly.

January 25, 1895.—Mrs. B. informed me that she heard and felt as well as ever. H. D., both ears, watch, five feet. The raw surfaces were now healed, leaving traces of their previous existence. No narrowing of either canal was observed. Inspection found no change in the drum membranes from the last examination. It is astonishing that no supplicative disease of the middle ear complicated the external manifestations. Fortunately for my patient, no permanent disturbance of her auditory perception resulted. The ocular symptoms, together with the cloudy urine, demonstrate that absorption of the acid had undoubtedly taken place.

When we consider the marked disturbance following the careless use of an antiseptic in this instance, it behooves us to be very explicit in giving directions to patients and furthermore impress us with the importance of decidedly emphasizing the dangers lurking in the generous suggestions of lay friends.

128 East Sixtieth Street.

The New York Board of Health's Diphtheria Antitoxine, we are informed, can now be had free of cost, provided the applicant presents the attending physician's certificate of inability to pay for it. Application must be made at the board's offices, in the Criminal Court Building, in Centre Street.

Changes of Address.—Dr. Percy R. Bolton, to No. 18 West Nineteenth Street, New York; Dr. John Winters Brennan, to No. 11 West Twelfth Street, New York; Dr. Lewis A. Conner, to No. 18 West Nineteenth Street, New York; Dr. Alexander B. Johnson, to No. 46 West Seventeenth Street, New York.

THE EFFECT OF PEPPERMINT INHALATION ON EXPERIMENTAL TUBERCULOSIS.

By EDWARD R. BALDWIN, M.D.,
ASSISTANT IN THE SARANAC LABORATORY FOR THE STUDY OF TUBERCULOSIS.

COINCIDENT with the clinical trials of the peppermint treatment described by Carasso,* carried on at the Adirondack Sanitarium, the following experiments were undertaken at the Saranac Laboratory under the direction of Dr. E. L. Trudeau:

1. To test the effect of the vapor of peppermint oil upon pure cultures of Bacillus tuberculosis as a preliminary to—

2. A test of its influence on the course of the disease in animals inoculated per tracheam and kept in an atmosphere charged with the vapor.

A few animals had first been treated subcutaneously by an emulsion of the oil, but very little of it was absorbed, and the method was abandoned as impracticable.

The experiments of Chamberland, Lucas-Championnière, Koch, and others have shown the disinfecting power of ethereal oils. The contact of the oil itself was found unnecessary to kill or inhibit the growth of bacteria.

The following confirms the result in the case of Bacillus tuberculosis with peppermint vapor:

January 27, 1894.—Twelve agar tubes were planted with pure cultures of Bacillus tuberculosis, twelfth generation. Six tubes were kept for controls, while the rest received three drops of ol. ment. pip. dropped on the cotton plug.

April 15th.—Good growth on all control tubes; none whatever on those treated with mint.

The theory stated by Carasso † as the basis of his treatment for pulmonary tuberculosis presumes the germicidal influence of peppermint, which, in volatile form, penetrates the diseased area and secretions and kills the bacilli.

To attempt an imitation of the conditions experimentally, intratracheal inoculations of tubercle bacilli were made in guinea-pigs and rabbits. The animals were then put into cages where the air was kept saturated with peppermint vapor.

17th.—Each of nine guinea-pigs of similar size and weight received 0.10 cubic centimetre of a watery suspension of a pure culture of Bacillus tuberculosis, first generation, on serum. A small incision was made over the trachea and the needle directed downward toward the lungs. The animals were held on their backs several minutes to permit the fluid to reach the bronchi.

Four days were allowed for them to become infected. Four pigs were then reserved as controls and the rest placed in a specially prepared tight box with a glass front. Air was admitted through a number of half-inch holes, over which was placed a wad of cotton kept saturated with ol. ment. pip. The holes were near the bottom of the box, while an outlet was provided in the top two inches in diameter and connected with a ventilator shaft leading outside the animal house. During the entire time the odor was sufficiently strong to cause laceration when the box was opened. The table shows the result:

---

† Loc. cit.
It was noted that the lungs of the treated animals were more congested than those of the controls, and two of them died with signs of tubercular pneumonia.

The virulence of the disease, aided, perhaps, by the confinement in the box and too irritating amount of peppermint, made the result of doubtful value. The next trial with rabbits is therefore more instructive.

August 2d.—Fourteen rabbits were inoculated in the same manner as above, but with a mixture of pure bonillon cultures of tuberele bacilli and crushed lung tissue of two tubercular guinea-pigs strained through sterilized muslin. Microscopic examination showed it to be free from contamination, and each rabbit then received two cubic centimetres of the fluid.

They were all put in pens for one week to permit infection to take place. Ten rabbits were then placed in a large box five feet by four feet eight inches by two feet four inches.

One end was closed by window sashes, at the bottom edge of which was left a space an inch wide for ingress of air. Along the latter opening, extending entirely across the box, was placed a tin trough, so arranged that the air passed over it. The trough was kept filled with oil of peppermint and covered with a gauze bandage to prevent the animals from getting into it.

In the top and rear of the box two-inch holes were bored at intervals for outlet of air.

The remaining four rabbits, together with one not inoculated, were confined in a box of the same shape and arrangement, save that it was just half the cubic content of the first and had no peppermint. These cages were placed together out of doors where the sunlight and air were freely admitted, while the animals were kept well fed. The volatilized oil was replaced daily, the odor being so strong as to be unpleasant all the time. The only effect apparently due to the inhalation was possibly an increase in appetite.

They showed no discomfort attributable to the vapor and often reclined close to the trough.

In all, the lesions were confined to the lungs and no differences were observed between control and treated animals. Tubercle bacilli were numerous in the softening areas, but few other bacteria were found.

Herewith is given the tabulated result:

Control.

DISEASES OF THE BRANCHIAL APPARATUS,
WITH REPORT OF SOME CASES*

By BENJAMIN B. CATES, M.D.,
PROFESSOR OF ANATOMY AND CLINICAL SURGERY
IN THE TENNESSEE MEDICAL COLLEGE, KNOXVILLE, TENN.

In seeking a sign, as it were, or explanation for many of the defects and deformities of the face and neck, investigators have traced them to some vitium incident to the fetus in embryo.

Now, the face is developed in embryo from a series of arches or processes separated by intervening sulci or sinuses, which processes are named by Rathke (who first described them) branchial. These arches divide into two

* Read before the Knox County Medical Society, February 28, 1895.
sets, named preoral and postoral, or visceral, according as they are situated in front or behind the bacular cavity.

The preoral arches unite with the fronto-nasal process from "the investing mass of Rathke." The fronto-nasal process is divided into a central, called also mid-frontal process, and two lateral ones. It is from this mid-frontal process coalescing with the lateral masses of the ethmoid derived from the trabeculae cranii that the intermaxillary bone and lunulae are formed—a failure of these parts to properly unite causing the defect known as harelip.

There are five postoral arches, the first of which is named mandibular, because from it is developed the lower jaw—hence the term mandible—the mouth being situated between the preoral and mandibular arches. Sometimes the buccal fissure extends back to the ear, constituting the condition known as microstomia.

The second postoral arch is called hyoid, and forms the incus, the stylo-hyoid, and lesser cornu of the hyoid bone. The third (thyreo-hyoid) forms the greater cornu and body of the hyoid bone, the rudiment of the thyroid cartilage, and the rest of the larynx. The fourth and fifth form the soft tissues of the neck, and hence do not form any special organ. These arches are separated by clefts which are formed previously to the thickening of the tissues which subsequently are called arches.

A portion of the first cleft persisting forms the Eustachian tube. The other clefts failing to unite properly are pathological and may give rise to a fissure, or, leaving a matrix composed of facial epiblastic or hypoblastic tissue, may be latent for an indefinite time, and later by proliferation give rise to a characteristic tumor—called by Roser a branchial cyst; by Langenbeck, a dermoid cyst of the sheath of the internal jugular vein; by Schede, a deep-seated atheromatous tumor; by Virchow, tumors of the branchial clefts; by Maunoir, hydrocele colli congenita; by Luschka, hygroma coli; by Lucke, an atheromatous cyst of the lymphatic glands.

However, the chief interest to us centers around some cases which show a vitiated development of the second or third branchial tract in the region of the hyoid bone, as is manifested by the appearance of a tumor evidently of the atheromatous variety; also a vitiated development of the fourth branchial cleft, evidenced by the appearance of fistulae of congenital formation and a congenital chondrofibroma of branchial origin. According to Matas (who published a most excellent monograph in the Medical News for December 2, 1892, on anomalies of the branchial apparatus, and with which I have taken considerable license for the literature), branchial fistulae appear in three different ways. They may be complete, connecting the external integument with the pharyngeal cavity; second, they may appear as blind external sinuses opening upon the cutaneous surface; thirdly, they may be blind internal sinuses opening only into the pharynx.

The seat of the external orifice is more commonly along the anterior border of the sternomastoid muscle and in the infra-hyoid region than elsewhere. Matas again quotes Lannelongue as classifying these fistulae topographically as—

1. Fistula opening into the concha of the ear.
2. Fistula opening into the supra-hyoid region which is common to the four branchial clefts.
3. Fistula opening into the infra-hyoid region.
(a) Median. (b) Lateral.

The treatment of these various affections has for its object the ultimate removal of deformity and the thorough eradication of every vestige of existing disease.

According to Senn, who made a most valuable contribution to the Reference Handbook of the Medical Sciences on branchial cysts, these tumors can be treated by (1) incision; (2) actual cautery; (3) seton; (4) puncture; (5) extirpation; (6) antiseptic drainage. No doubt, in the vast majority of instances, each case will be treated according to the exigencies of the case. However, when feasible, extirpation offers the best, the most thorough, and the most radical method. Again, in very young subjects, and in adults with cysts inaccessible to other operative measures, Senn recommends antiseptic drainage as a temporary measure, stating that it is sometimes followed by a permanent cure.

The diseases of the branchial apparatus that have come under my notice are reported seriatim as follows:

Case I.—Eva B., at the time of operation twenty-five years old. When she was nineteen years of age a tumor of the left side of the neck was noticed, which continued to increase steadily in size. It gave trouble only by reason of its increasing deformity. There was no pain connected with it, nor did it interfere with respiration or deglutition. Examination showed a tumor of about the size of a hen's egg on the left side of the neck in the superior carotid triangle; it was not painful to the touch, and it was freely movable from side to side, but not from above down.

Operation.—The tumor was removed by incision behind the sternomastoid muscle. The spinal accessory nerve passed over the tumor. The tumor was sacculated and adhered to the sheath of the carotid vessel. It was removed with the sac in toto. The interior of the tumor on incision showed a mass of atheromatous, brain-like matter. The patient rallied, and the wound healed kindly per primam intentionem. One point of great interest in this connection is that the pupil on the affected side after the operation remained dilated for a long time, interfering with the vision, although there never has been any flushing or sweating on that side. This inequality of the pupil disappeared to a large extent, and the vision is quite as good as before, but even now, some six or seven years since the operation, the pupil occasionally becomes dilated.

Case II.—George C.; white; nine years old; healthy. Family history good. When about five months old his mother, when bathing him, noticed a small drop of pus on the side of the neck, which, on pressure, discharged about half a fluidrachm of creamy substance. Examination shows, about an inch and a half above the right sterno-clavicular articulation, along the anterior border of the sternomastoid, a slight enlargement in the skin, in the center of which is a minute orifice so small as to barely admit the end of a filiform bougie for a short distance. There is no communication with the mouth. This sinus discharges a creamy-like matter once every two or three weeks.

Case III.—Andy O.; white; eighteen years of age; healthy. Family history good. Three or four weeks after his birth his mother noticed one morning, while bathing him, what she thought was a small thread on the side of the neck, which,
when detached, left a small opening which discharged several drops of a yellow, creamy-looking matter. This has since discharged half a fluid ounce of a creamy liquid periodically every two or three weeks. This is more likely to discharge freely when the patient becomes overheated.

Examination shows, about half an inch above right sterno-clavicular articulation, along the anterior border of the sterno-mastoid muscle, a minute red spot like a flea-bite, in the center of which is an orifice so small as to be scarcely distinguishable. This, however, will admit the smallest filiform bougie passing along the neck toward the hyoid bone two inches or more. As the probe passes toward the hyoid bone the patient begins to cough. On reversing the probe it will pass down toward the right sterno-clavicular articulation for an inch.

Case IV.—Albert R.; fourteen years of age. He was the youngest of five healthy children. Family history good. Has a small congenital growth (evidently of branchial origin) on the tragus of the left ear, one centimetre in length, which is slightly club-shaped. It projects forward and outward from the tragus.

The following case coming under my notice by courtesy of Professor C. P. McNabb, M. D., accentuates in a marked degree the influence of heredity upon branchial fistula, the disease in question occurring in three generations of the same family:

Case V.—Robert B.; white; bridge builder; aged twenty-eight years. He was the third child in a family of six children. The mother had fistula in both ears in the upper extremity of the helix, where it joins the side of the head, and also in the infra-hyoid region, on either side of the sterno-mastoid muscle above the sterno-clavicular articulation. Two sisters older than himself had incomplete fistula in the upper extremity of the helix of either ear extending toward the concha, but none in the neck. One brother younger than himself has complete fistula in the helices of both ears extending into the upper extremity of the concha, so large as to be quite visible for some distance. However, he has no fistula in the neck. Again, also, this patient has a female child three weeks old with incomplete fistula in the upper extremity of the helix of the right ear.

Examination of the patient shows that the upper extremity of the helix of either ear has an incomplete fistula extending downward toward the upper extremity of the concha in either ear. On the right side, in the infra-hyoid region along the anterior border of the sterno-mastoid muscle, about an inch and a half above the sterno-clavicular articulation, there is a minute opening so small as to barely admit the smallest probe of a hypodermic syringe. This opening leads upward to a small subcutaneous tumor of about the size of a cherry just below the hyoid bone, and on reversing the probe it descends for a short distance. By squeezing, a transparent, maceoid, jelly-like substance can be made to exude from the opening. However, after irritation, as by a collar rubbing, a yellowish, creamy-like substance will escape from the fistula. On the left side, symmetrically opposite the opening on the right side, another small opening exists in the skin; this one, though, is quite shallow, and does not have any secretion escaping from it.

The Sloane Maternity Hospital.—The Esculapian announces that on the 1st of July the present house physician, Dr. Ervin A. Tucker, is to become an assistant attending surgeon to the hospital, also tutor in obstetrics to the second-year men in the Medical School of Columbia College (College of Physicians and Surgeons), and to be succeeded as house physician by Dr. George Livingston Brodhead.
MINOR PARAGRAPHS.

A LIBEL SUIT WON BY A YOUNG DOCTOR.

About two years ago some of the New York newspapers published fantastic accounts of certain unconventionalities alleged to have taken place in a Fifth Avenue boarding house in which two young doctors, Dr. Achilles E. Davis and Dr. B. F. Parrish, happened to have quarters. These young gentlemen were held up before the public as having been implicated in scandalous goings-on in the house, and certainly must have been injured materially in the estimation of those of their acquaintances who are accustomed to give credence to newspaper gossip. Dr. Davis brought a suit for libel against the Sun Printing and Publishing Association, and we are very glad to learn that the jury brought in a verdict for $2,500 in his favor. We are informed that this was but a test suit, and that the other offending newspapers will be sued by Dr. Davis and Dr. Parrish. By pursuing this course they are not only vindicating themselves, but doing a public favor, and we hope they will meet with complete success in their suits.

AN IMPORTANT CONTRIBUTION TO DIPHTHERIA ANTITOXINE LITERATURE.

One of the weightiest pieces of testimony in favor of the antitoxine treatment of diphtheria appeared in the last number of the Archiv für Kinderheilkunde. It is an article by Dr. Adolf Baginsky and Dr. Otto Katz. Dr. Katz gives very full histories of a hundred and sixty-seven cases of diphtheria treated with the Aronson antitoxine. The authors say that at the outset they were very skeptical concerning the antitoxine treatment, but that when they had seen case after case of the gravest kind take a most favorable turn after it had been employed they came to the conclusion that it was time to reconsider. Their present impression is that, while the antitoxine is not a cure-all, it will exert the most favorable influence in the majority of the worst cases of diphtheria.

"ENTERPRISE" OR INSOLENCE?

An esteemed member of the faculty of one of our New York medical schools has sent us certain documents lately received by him from a Philadelphia firm of publishers of medical books. Our friend asks: "Isn't this sort of insolence worthy of an editorial blast?" Mere mention of the nature of the inclosures will, we think, be all that is necessary. One of them is a printed form for the professor to fill out and transmit to the clerk of the college. It reads as follows: "Please see that the following book, viz., . . . . . . . is given a prominent position in the printed "text-book list" under the department of . . . . . . . in the next college catalogue and announcement." The other is a blank for him to use in reporting to the publishers the fact that he has carried out their wishes, in estimating for their benefit the number of copies of the book that the class would probably buy, and in intimating where a new edition of it may be sent to him, if any is issued.

ITEMS, ETC.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 28 to May 11, 1895:

Snyder, Henry D., First Lieutenant and Assistant Surgeon, is granted leave of absence for two months, to take effect upon the conclusion of his examination to determine his fitness for promotion.

Champtom, Louis W., Captain and Assistant Surgeon, will report in person to the president of the examining board appointed to meet at Denver, Colo., on May 14, 1895, for examination for promotion.

Ewen, Clarence, Major and Assistant Surgeon. The leave of absence granted him on account of sickness is extended three months.

Johnson, Richard W., Captain and Assistant Surgeon, is relieved from duty at Washington Barracks, District of Columbia, and ordered to Fort Huachuca, Arizona, for duty, relieving Wilcox, Timothy E., Major and Surgeon. Major Wilcox, on being thus relieved, is ordered to Fort Schuyler, New York, for duty.

Matthew, Washington, Major and Surgeon. The extension of leave of absence on surgeon's certificate of disability granted him is further extended four months.

Waters, William E., Major and Surgeon, is granted leave of absence for one month and fifteen days, to take effect on or about June 16, 1895.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending May 11, 1895:

Baker, J. W., Passed Assistant Surgeon. Detached from the U. S. Steamer Enterprise and ordered as recorder of the Naval Medical Examining Board.

Barnew, M. W., Assistant Surgeon. Resigned from the navy, May 7, 1895.

Boyd, Robert, Assistant Surgeon. Resigned from the navy, May 8, 1895.

Drennan, M. C., Surgeon. Ordered for examination preliminary to promotion.

White, S. S., Passed Assistant Surgeon. Ordered to the U. S. Steamer Bancroft, June 8, 1895.

Wilson, H. D., Assistant Surgeon. Detached from the U. S. Steamer Vermont and ordered to the U. S. Steamer Monongahela.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 14, 1895:

HOW TO MAKE IODOFORM GAUZE.

New York, May 15, 1855.

To the Editor of the New York Medical Journal:

Sir: At the request of a number of gentlemen who have attended my clinics I desire to make public through you my formula for making a surgical dressing impregnated with iodoform. Fine-mesh gauze is steam-sterilized. It is then dried. After drying, the gauze is soaked in a twenty-per-cent. solution of iodoform in ether for ten minutes. It is taken out and the excess of ether wrung out with the hands. The gauze is now placed in a basin and covered with a towel. It is left for twelve hours in a warm room, after which time it will be found that the ether has entirely evaporated. The gauze is now of a greenish-blue color, presenting the characteristic starch-iodine reaction. It is unfit for use in this state, the iodine being too free.

The next step is to soak the gauze for twelve hours in a watery solution of bichloride of mercury, 1 to 4,000, for an hour or so. This acts as a "fixing agent," and the beautiful golden color of iodoform again appears. The gauze is now wrung as dry as the hands can make it and preserved in glass jars.

Prepared in this way, the iodoform is not held in the gauze in mere mechanical association, but is in every last cell of the fiber (cotton) of which the gauze is composed. The advantage of this is manifest: such a dressing can not be poisonous, as the iodoform is not absorbed. The addition of discharges and blood to the gauze again turns it greenish-blue, showing that the iodine is again in a free state. So, when the dressings are saturated they are yet sterile. In cavity wounds, there being no glucerin in the gauze, no serous exudation is induced. This material has been used by me for five years or more, and I may say it has largely influenced the results as well as after-treatment of my operations. I estimate that I make one dressing where three are made when other gauzes are used.

For instance, I leave a Mnikulic packing in the abdomen for two weeks and when it is removed there is no pus, and no rise of temperature while it is in.

In one case where I did a successful hysterectomy for puerperal septiaemia the last piece of gauze was not removed before the tenth day. In curettage for gonorrhoeal and septic endometritis the gauze stays in for five or more days.

In my method of operating for ventral hernia, the first dressing is made in from ten to fourteen days.

Ablations of the uterus are not dressed before the tenth or twelfth day.

This is the only dressing I have ever found which is powerfully antiseptic, is non-irritant to the tissues, and remains sterile when soaked with discharges from an infected area.

It is perhaps well to mention that the dressing is prepared under an aseptic procedure as precise as that employed at an operation.

As to quantity that may be used: five yards long, one yard wide, in a puerperal uterus; sixteen yards long, four inches wide, in an obliteration of the pelvic cavity; nine yards long, four inches wide, after a surgical resection; and in no instance has there been the least evidence of iodoform intoxication.

So far as the chemistry of the procedure is concerned I have been told it is as follows: When the gauze is green after the ether has evaporated there is iodide of starch and there is free iodine; when the bichloride has been added there is bichloride in the starch and there is iodoform; when the bichloride is

Births, Marriages, and Deaths.

Married.

Wertenbaker—Girardeau.—In Milton, Mass., on Tuesday, April 30th, Dr. Charles Poin Dexter Wertenbaker and Miss Alice De Lancey Girardeau.

Died.

David.—In Dillen, S. C., on Saturday, May 4th, Dr. William J. David, in his sixty-eighth year.

Forsty.—In Providence, on Saturday, May 11th, Dr. Frank L. Forsyth, aged forty-one years.

Halsey.—In Brooklyn, on Tuesday, May 7th, Dr. John Condit Halsey, in his eighty-third year.

Nichols.—In Canandaigua, N. Y., on Wednesday, May 8th, Dr. Henry W. Nichols, aged sixty-five years.

Porteous.—In Poughkeepsie, N. Y., on Saturday, May 11th, Dr. James G. Porteous, aged fifty-six years.

Sutherland.—In Washington, on Friday, May 10th, Dr. Charles Sutherland, formerly surgeon general of the army, in his sixty-fifth year.
The constant characteristic phenomena of the disease gradually increased until he could hardly be persuaded to step out of his house, and was quite wretched if it became necessary for him to cross the street in front of his own door. He became more and more the victim of terror of space, often feeling lost in the room in which he was occupied in his daily duties. He at length underwent a gradual mental change which resembled a mild form of senile dementia, though he was not in years in which this degeneration would be expected. His bodily health became depressed, and at last he was reduced to a considerable degree of feebleness. He died a short time ago, in consequence of influenza. There was at no time any real improvement in the functional disturbance of the mind, though he would appear at times less distressed by the idea of space than at others. This patient presented another point of special interest in the fact that he had been from a child totally blind, and it is worthy of question how far the study of agoraphobia in this class of individuals might contribute to the establishment of the at present theoretical so-called "space-organ," to which for years physiologists have been directing some attention.

It does not seem to me that agoraphobia should be properly classed among the affections accompanied by "fixed ideas," as suggested by the writer of the article alluded to. In true agoraphobia there are no indications of active mental disturbance in any other direction. There is no delirium, the patient is not subject to hallucinations of hearing, he is not influenced by impulsive emotional explosions or crises of any convulsive character. He is simply the victim of an uncontrollable and overpowering terror at the idea of extended space about him. He fully understands that no real occasion for his terror exists; but his frame of mind is similar to that of the traditional ghost-seer, who also knows that his fears are utterly groundless. No one would think of pronouncing such a person insane, and there would seem to be no great reason for classifying agoraphobia among the established forms of mental diseases. The result in my case fully bears out the prognosis indicated by Dr. Taylor, in which he states that he does not share the hope of the patient as to the future. The careful record of further cases of this interesting condition is much to be desired.

Albert N. Blodgett, M.D.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of March 6, 1895.

The Vice-president, Dr. Parker Nyses, in the Chair.

Rachitic Deformity of the Chest.—Dr. W. R. Townsend exhibited a little boy with a rachitic deformity of the chest, consisting in a very marked depression of the lower portion of the sternum exactly in the median line. There had been apparently little or no interference with the breathing capacity, for there had been a compensatory projection of the chest posteriorly. There had been no displacement of the heart. The question of prognosis was, he said, interesting as regarded the effect of the deformity on the function of the lungs. It would seem that by proper gymnastic exercises sufficient expansion of the lungs could be secured. The mother of this child had stated that she had not noticed this condition until after an attack of whooping cough two years before.

Dr. E. Le Feyre said that he had seen at the clinic a number of children with such deformities of the chest, but most of

changed to calomel by blood, etc., the iodine again becomes free and the dressing is again greenish-blue. But I can not say whether this is true so far as the chemistry is involved. Certainly marvelous results are obtained with it. W. R. Pryor, M. D.

YELLOW FEVER.

JACKSONVILLE, Fla., January 29, 1895.

To the Editor of the New York Medical Journal:

Sir: Not the least interesting among the items in your Journal are the weekly reports of infectious diseases in New York.

In the present issue, January 26th, I notice the report of a number of cases of scarlet fever, measles, diphtheria, and small-pox, with a large percentage of deaths from scarlet fever and diphtheria.

These are universally regarded as actively contagious and oftentimes fatal diseases; yet there is no excitement, no alarm, no approach to a panic in the city or the country.

Suppose the occurrence of a case, or even a "suspicious" case, of yellow fever in the South, a circumstance extremely probable in the existing unsanitary condition of our cities, what, then, would be witnessed? Every paper in the Union would publish the fact with glaring headlines: surgeons of the Marine-Hospital Service and other so-called "guardians of health" would flock to the doomed locality; fugitives in great numbers would rush from their comfortable homes without the means to be comfortable elsewhere; quarantine restrictions would be enforced; travel would be arrested or impeded; business would be suspended, for an armed cordon would surround the ill-fated city; the well would be imprisoned with the sick within the limits of the infected locality, to increase the number of cases and multiply the deaths; families occupying houses within five or six hundred feet of the victim would be forcibly ejected from their homes; the families of the sick would be violently separated from their suffering loved ones; individual, municipal, and State rights would be ignored or disregarded; appeals for aid to the charitable people of the country would be issued; and the thousands of dollars in money and supplies thus raised would be squandered by self-appointed "sanitary committees."

And yet, by common consent of those who have personal knowledge of yellow fever, it is not communicable from person to person; it is not at all contagious. Dr. Sternberg, surgeon general of the army, declared that the yellow fever would not pass from the sick to his family or to his family. Is there any explanation of this gross, cruel inconsistency upon the basis of facts and common sense?

George Troop Maxwell, M. D.

AGORAPHOBIA.

390 Boylston Street, Boston, May 7, 1895.

To the Editor of the New York Medical Journal:

Sir: In the issue of your valuable Journal for March 30th there is a very interesting account of a case of agoraphobia from the pen of Dr. Neville Taylor. This condition is so rare that any contribution to its study is of importance. I ask the courtesy of your pages to allude to a case under my own care, some years ago, reported in the Boston Medical and Surgical Journal, vol. cviii, p. 407, which presented an almost classical array of the known symptoms of this obscure malady. I am now able to add the subsequent history of this patient, who for a period of years has been under my observation.
them had been older, and they had given a history of rickets. The parents had frequently stated that they had not observed the deformity until after an attack of some acute pulmonary disease. Most of the rachitic deformities of the chest seen in children, he thought, could be accounted for on the ground that the air could not gain access to the lungs in a sufficiently rapid manner, and hence there would result a vacuum, unless depressions of the soft and bony structures occurred. Examination of the boy had shown but little interference with the vital capacity. Along the depression of the sternum the heart could be felt pulsating. Unless the child should have a severe attack of bronchitis or of diphtheria or any condition that interfered with the air entering the lungs freely during inspiration, it was not likely that this deformity would be increased. The chief defect appeared to be in the sternum, and as a result the support support ordinarily given to the ribs had been insufficient. The liver dullness had begun about two finger-breadths below the nipple line on the right side. It seemed to him that the prognosis was not unfavorable.

Dr. Robert T. Morris thought that while the bones had been so soft, it would have been easy to slip a hook under the xiphoid cartilage and make it convex, and it could be kept in that position by pressure made on the ribs on either side. This could be accomplished mechanically, but whether or not this would be productive of any material benefit to the child was another matter.

Spontaneous Rupture of the Mastoid Cells.—Dr. Godshall Bacon presented a girl, two years of age, who had been first seen on November 9, 1894. The right ear had begun to discharge nineteen months before, and four months ago a swelling had suddenly appeared behind the ear, and had subsequently ruptured spontaneously. When first seen, on November 9th, there had been a large sinus directly over the antrum, and thick, foul-smelling pus had been discharging from the ear. On the same day a long incision had been made down to the bone, just behind the attachment of the auricle, and a sequestrum, about an inch by three quarters of an inch, had been removed. The entire cavity had been scraped and many unhealthy granulations taken away. The wound had been packed with iodoform gauze, after having been syringed with bichloride solution (1 to 5,000), and bandaged. As a specific taint had been suspected, iodide of iron had been administered to improve the general health. Healing had been prompt.

The speaker exhibited the sequestrum and also photographs showing the pulmonary cells alone, the partly pneumatic and partly diploëtic cells, and the more or less sclerosed ossous tissue.

Dr. Walter C. Wood said that an interesting case of this kind had come under his observation. A man had entered the hospital in a somewhat apathetic condition. The house physician had made a diagnosis of alcoholism at the time, but on examining him later the speaker had found well-marked evidence of mastoid disease. About half an ounce of pus had been evacuated from beneath the periosteum and from the cells. It had been then ascertained that there had been mild symptoms existing since early in January. This patient had been prominent in a recent large strike, in the management of which he had been severely criticised for his peculiar mental condition. On admission, his pulse had been 60 and his temperature 100° F.

Dr. H. H. Seabrook said that some time ago he had seen a case of brain tumor. One of the best-known neurologists in this city had diagnosticated the case as one of abscesses of the brain following middle-ear disease. The man had had a history of a discharge from the ear some five years previously. When first seen he had had facial paralysis and a hemiplegia of the opposite side, indicating that the tumor was in the lower portion of the medulla. As a matter of fact the tumor had been found post mortem to be situated in the tempo-sphenoidal lobe. It was remarkable, the speaker thought, that this neurologist should have alleged that the symptoms present had been due to an otosclerosis which had ceased some years before.

Dr. Chandler thought these cases illustrated the importance of early treatment. Two months ago he had been called to a child with otitis media. Shortly afterward there had been evidence of mastoid trouble. The abscess had been evacuated, and after two or three weeks a small piece of bone had been discharged. There had been a communication with the mastoid cells, but, although the operation had been done less than two months ago, the wound had nearly healed.

Dr. Bacon said that he had only presented this case on account of the occurrence of spontaneous rupture in a child. He believed that if mastoid disease was treated early, there would rarely be occasion for operation. If a natural or an artificial leech was applied directly over the mastoid cells and then ice used in the first stage of the inflammation, instead of poultries and blisters, many cases would be aborted.

He also wished to make a most emphatic protest against the use of heat applied to the mastoid process, especially in the way of poultries, also against blisters. He preferred, in the early stage, the use of cold, applied by the ice bag or Leiter coil, and if this did not succeed, then the mastoid cells should be opened.

Chronic Prepatellar Bursitis: Excision of the Entire Bursa: Complete Recovery.—The Vice-president reported the following case: G. A., aged twenty-three years. He was admitted to Lebanon Hospital on January 29, 1895. His general health was excellent. Previous history good. Patient is a piano mover and porter, and frequently brings heavy pressure on his knee. He states that there was a slight swelling over his left knee which did not trouble him till four weeks previous to his admission. At that time the prepatellar bursa became more swollen, and was very painful and tender. When he was admitted to the hospital the region in front of the knee was swollen and red. Examination showed the bursa to be distended with fluid. Hard masses could be felt which appeared to be free bodies. The sac was evidently considerably thickened. The patient walked with difficulty and could not flex the knee. An operation was performed on February 4th.

Under careful aseptic conditions the bursa was dissected out entire. The incision through the skin was made in the long axis of the limb. The separation of the sac was not difficult except where it was attached to the joint capsule. Healing took place by primary union and the patient left the hospital in ten days, with perfect function in the joint.

Appendicitis.—Four cases were reported by the Vice-president.

Case I.—Appendicitis; second attack; large paratyphilitic abscess; operation on the fourteenth day of disease.

David S., aged forty-five years; general condition was good; general history negative, except as to one previous attack of appendicitis. Admitted to Lebanon Hospital.

About a year previous the patient was in Lebanon Hospital with an attack of appendicitis which resolved without operation.

Thirteen days before coming to the hospital this time, the patient was taken ill with abdominal pain and fever and gave the ordinary history of an appendicitis. His physician treated him with leeches, blisters, and poultices, and as he failed to improve sent him to the hospital. On admission the patient had rapid pulse and coated tongue, and the temperature was 103°. A well-marked swelling was found in the right iliac region. It was tense and showed signs of fluctuation, and a large paratyphilitic abscess was diagnosed.
May 18, 1895.] PROCEEDINGS OF SOCIETIES. 681

A simple incision was made, and pus was found when the abdominal wall was cut through, about a pint being evacuated. The cavity was explored with the finger, but further than that the appendix was not sought and no trace of it was found. The cavity was treated as a simple abscess cavity. The patient's temperature fell after the operation and soon reached normal. He made a rapid and uneventful recovery.

Case II.—Acute primary appendicitis: localized peritonitis causing dense adhesions; ruptured appendix; small amount of pus; large enterolith; operation on the fifth day.

John D., driver, aged twenty-five years. He was admitted to Lebanon Hospital, December 15, 1894.

Previous history good and negative. No history of any previous attack. Four days before admission he was taken suddenly ill with a severe attack of vomiting and abdominal pain, and later fever. He was constipated at the time. When admitted he had a temperature of 102° F., pulse, 100. His face had an anxious expression, and the tongue was coated. He complained of pain in the abdomen. Palpation showed a well-marked tumor in right iliac fossa, with greatest point of tenderness over the seat of the appendix. From the history and symptoms it was decided that he had a recently ruptured appendix, surrounded by dense and firm adhesions. An operation was performed on December 15, 1894. The ordinary incision at the outer side of the right rectus muscle, about four inches in length, was made through the abdominal wall. The intestines were found to be firmly matted together by remarkably thick adhesions. The coherent mass was turned inward, the general cavity carefully protected by flat sponges, and the appendix sought for. It was found behind the cecum in a dense mass of adhesions. The appendix was distended with pus. There was about a drachm of pus outside of the appendix. A small ragged opening in the appendix was found about an inch from its base, which had been caused by sloughing. Through this opening could be seen a body which proved to be an enterolith of about the size of an ordinary hazelnut. The appendix was firmly attached to the cecum and its separation was difficult. The peritoneal coat was stripped up to make a flap, which was stitched over the stump after the appendix was ligated and removed. Two silk sutures were passed through the abdominal wall and left untied till granulation had progressed well. The wound was packed with iodiform gauze. The patient made a prompt and uneventful recovery.

Case III.—Acute suppurrative appendicitis; dense adhesions; large, deep-seated abscess; laparotomy; recovery. Operation on the eighth day.

Miss McK., aged fifteen years; previous and general history good. Was well until January 1, 1895, when she was taken ill with abdominal pain and tenderness, greatest over the appendix. Her temperature was elevated and pulse accelerated. The case proceeded as usual for a few days and on the fourth and fifth days the symptoms were all better. On the sixth day she again had increased pain and fever, and more frequent pulses. I was called to see her on the seventh day and found her with temperature, 101.5° F.; pulse, 129. There was a well-marked tumor. Diagnosis was made of ruptured appendix, with large, deep-seated abscess. Immediate operation was proposed and consented to, and the operation was performed on January 7, 1895, at the patient's home. Dr. Joseph Gray and Dr. O'Brien assisted.

The ordinary incision was made at the outer side of rectus muscle. On opening the abdomen the intestines were found to be firmly bound together by thick adhesions. This mass was deflected toward the median line; the general cavity was protected by flat sponges. Then an abscess was carefully opened and pus was sponged away as it escaped. This abscess contained about two ounces of pus, and was situated behind the cecum at the normal site of the appendix. After the pus had escaped through the small opening the cavity was thoroughly opened by tearing apart the adhesions, and an attempt was made to find the appendix. This attempt was not successful, and it was not persisted in long, for the following reasons: 1. Because it was doubtful if there was an appendix to find, as it was not unlikely could have been shed by sloughing. 2. Because it was considered dangerous to break up the adhesions beyond a moderate extent.

Two provisional sutures of silk were passed through the abdominal wall; the wound was packed to the bottom of the cavity. The patient progressed well. She has been up and about since the third week after the operation. A small sinus still persists, now about an inch in depth. This seems to result simply from slow healing.

Case IV.—Acute gangrenous appendicitis; perforation; no adhesions; general suppurrative peritonitis; celiotomy; removal of appendix; toilet of peritoneal cavity. Recovery.

M. L., aged fifty-one years. His general health was good, also his past history, except for some attacks of indigestion. No history of previous appendicitis. Was well until February 1st, when he was taken suddenly ill early in the morning with vomiting and severe abdominal pain. He did not send for his physician, Dr. Gray, until Saturday afternoon at about four o'clock. Dr. Gray found him in a chill with a temperature of 103°, pulse, 130. The doctor examined him and made the diagnosis of appendicitis, and advised early consultation and probable operation. He very properly applied ice to the abdomen, had the patient kept on his back in bed, administering no opium.

I saw the patient with Dr. Gray at eight o'clock on the same day, thirty-six hours after the first symptoms. Temperature was then 100.2°, pulse 100, but on slight exertion went to 120. The patient's face was deeply flushed and rather bluish, showing poor capillary circulation. He was rather lethargic, and complained of but little pain. There was great tenderness over the seat of the appendix; there was very marked tympanites; the distention was so great as to obscure the result of palpation; no localized tumor could be felt, but the greatest resistance in the muscles was over the appendix. Immediate operation was proposed and assented to.

It is interesting to note here that at this time his symptoms seemed to show improvement. His pain was less severe, his temperature had fallen two degrees, and he said he felt better, but there was something about his expression and the character of his pulse that prompted me to say that I feared he had grave abdominal sepsis, and that his heart might not stand the shock of the operation, which was performed. The ordinary incision along the outer margin of the rectus muscle was made; owing to the distention its length was made about six inches. Before the peritoneum was opened it bulged out into the wound like a coil of intestine. On opening the peritoneum a quantity of sero-paracentic fluid escaped, and the wound was filled with coils of dark-colored, swollen, distended, inflamed intestine, bathed with this fluid, and coated over and there with patches of thick, grayish-colored lymph. The peritonitis was general and there were no adhesions. The large swollen appendix was found behind the cecum attached by a short mesentery. From a minute opening near its base there escaped some soft material which seemed like fecal matter and pus. The appendix was loosened, ligated, and removed. The stump was canerized and then covered with a peritoneal flap.

The patient's condition was bad, and his pulse failed a good deal in character although the operation was not a long one. Although it was desirable on account of the general peritoniti-
to do a median section and thoroughly cleanse the cavity, it was deemed unwise to do so on account of the patient's condition. The incision was rapidly increased in length, and through it a large amount of the intestine was brought out and washed and wiped with sterilized sponges; then the abdominal cavity was flushed with boiled water; finally, the intestine was returned, and the wound packed with iodoform gauze. This packing was sewed in to prevent protrusion of the distended intestines.

The patient was put to bed in about an hour from the time of beginning the etherization. His pulse was very weak, but not very rapid. For twenty-four hours his case seemed hopeless. His pulse continued weaker, and the distention of his abdomen was something remarkable, and he certainly had paresis of the intestines from the septic peritonitis, so that his case seemed more like one of obstruction than of inflammation. A saline was administered as long as his stomach would tolerate it, and several high enemias were given. At the end of twenty-four hours he passed some gas per rectum and later some fecal matter was passed with one of the colon flushings. The patient at once began to improve and has made an uninterrupted recovery. Now, at the middle of the fourth week, the wound is almost entirely healed.

Dr. J. M. Brook said that he had seen several cases of appendicitis in women in which it had been difficult to make the diagnosis between pyosalpinx and appendicitis. Vaginal examination in one case had shown a mass on the right side behind the uterus, while the menstrual symptoms had pointed rather to a pyosalpinx. At the operation, both pyosalpinx and appendicitis had been found to be present. In such a case, it was not possible to say before operation just what condition was present. He mentioned this to ascertain the experience of others in regard to appendicitis in women.

Dr. Robert T. Mooms said that the temperatures in the cases reported by Dr. Symes had seemed to him rather higher than the average. It should be remembered that when the colon bacillus existed apparently in pure culture, the temperature would seldom fluctuate more than one degree on either side of 100°, and it might remain perfectly normal during all the stages of a most destructive attack of appendicitis. The pulse, however, was prone to fluctuate considerably, reaching perhaps a hundred and thirty or a hundred and forty beats a minute, and being small and thready. Aside from this disagreement of the vital signs, there was but little to indicate the severity of such cases. In one or two instances in which he had seen small collections of pus, and nearly pure cultures of streptococci, there had been high temperatures—103° or 104°. He wished very much that other surgeons would pursue this line of investigation, and so furnish corroborative evidence regarding the effect of certain bacilli on the vital signs. It should not be expected that the appendix was destroyed when abscess occurred. It was wise in a few cases to do as Dr. Symes had done—not search far for the appendix if the patient was quite feeble—but we should not believe that the appendix was necessarily destroyed in such cases. He had removed appendices which had been nearly whole, years after the evacuation of large abscesses. The concretion referred to had probably been phasicitic. The majority of them were fecal or phasicitic. Occasionally, a concretion was composed of more than one half of fat, probably due to retrograde fatty change in the lymphoid cells. According to his experience, the family physician was apt to feel considerable concern lest the fistula remaining after appendicectomy operations would not heal. He had not found it necessary to perform secondary operations in such cases, for although they were often quite slow in healing, this almost invariably had occurred without the necessity of operative interference. It was not uncommon to observe an apparent improvement in the condition of the patient when the appendix had become gangrenous. This sudden improvement in the symptoms often led the attending physician, as well as the family of the patient, to urge a postponement of the operation. It was sometimes difficult to distinguish between appendicitis and pyosalpinx; they not infrequently occurred together. He thought that the appendix often became infected secondarily from adherent oviducts.

Dr. Wood said that the vital question was as to whether or not the appendix should be removed in cases presenting acute symptoms. His experience had taught him that it was not wise to be too radical in cases in which the appendix had been firmly bound down. Out of sixty cases that he had observed there had been but one permanent fistula, and this had been due to sloughing of the wall of the oesum. This could, of course, be cured if the patient would consent to operation. The Mikulicz drain, consisting of a bundle of lampwicks, was very valuable in these cases, and was an exceedingly potent means of producing drainage. The edges of the wicks were placed so as to radiate in every direction. Their action was astounding.

Dr. Houghton thought it was quite possible in the early stage of appendicitis to mistake an accumulation of fecal matter in the colon for a beginning appendicitis. This had occurred to him a number of times.

Dr. W. Evelyn Porter said he had had two or three cases in which the symptoms had been due solely to an enteritis brought about by fecal impaction. Unless there was very positive evidence of inflammatory process outside of the appendix, it seemed to him that the bowels should be very thoroughly opened in order to remove this possible source of error. The reader of the paper was to be congratulated on the results obtained in his cases, particularly in the last one. In the septic cases one of the greatest difficulties to contend with was the absolute paralysis of the gut and the impossibility of moving the bowel. Undoubtedly in the case reported a certain amount of sepsis had remained after the operation, and yet as soon as the bowels had moved there had been a subsidence of these symptoms. It was the rule that where a free escape of gas and a fecal movement could be secured, recovery ensued. Any suggestions regarding the various means taken to accomplish this, he felt sure, would be instructive and acceptable to all present.

In operating in quite a large number of cases of tubal disease he had been surprised at the very variable situation of the appendix. In two cases he had found the appendix attached to the left Fallopian tube and had looked in the adherent mass on that side; in a great number of cases the appendix had been found adherent to the Fallopian tube on the right side. Where there was no evidence of general sepsis it seemed to him often wiser to make no attempt to remove the appendix, as in the effort to do this there was great danger of infecting the peritoneal cavity.

Dr. George P. Brooks said he had been interested in the remarks regarding the association of appendicitis and salpingitis, and the difficulty, at times, of determining, even at autopsy, at which point the disease process began. With two diseases so common as these it was not surprising that they should be found associated, nor difficult to understand that they might have originated independently without causal relation one to the other. In autopsy work the appendix was not very infrequently found adherent to the uterine appendages of the right side, sometimes due to appendicitis and sometimes to salpingitis with localized peritonitis.

The speaker objected to Dr. Morris's statement that appendicitis was frequently due to salpingitis, unless he referred sim-
of severe, class there had it on labeling. A perforation had existed about its middle, and the tissues from this point to the site of operation had been extensively infiltrated with pus. Subsequent microscopic examination of the material removed at the operation had shown a normal Fallopian tube and ovary, with diffuse purulent infiltration of the tissues of the broad ligament, showing clearly a primary, perforating appendicitis, with secondary suppuration of the tissues of the broad ligament. The symptoms had been such as to suggest primary salpingitis.

Dr. J. B. Guass said that he had seen many similar cases, most commonly at the sigmoid flexure. The giving of cathartics in such a case was by no means free from danger. If the obstruction was very great, this increased peristalsis might give rise to such pressure as to seriously jeopardize the integrity of a weak spot. He did not think any one doubted the propriety of opening an abscess when it could be detected and located, and hence the whole matter of operating on cases of appendicitis was one of accuracy of diagnosis. At one time he had been asked to see a case of appendicitis in consultation. Examination with the hand per rectum, under ether anesthesia, had enabled him to feel an abscess. This he had punctured and drained through the rectum. He would like to know more about the value of rectal examinations in these obscure cases.

Dr. Robert A. Murray said that he thought Dr. Symns was to be congratulated upon the recovery of his patient with septic peritonitis, for certainly it was exceedingly rare for such cases to terminate so happily. In his experience appendicitis had occurred in three different classes. The first class comprised those in which there had been perforation, but strict limitation of the abscess. In these cases there might be little or no elevation of temperature, and yet the character of the pulse and the aspect of the patient should lead the careful physician to perceive the danger. In the second class there was a history of previous rupture. (The patient had recovered from its immediate effect.) Here an operation was always demanded, and, if not done, the patient would sooner or later succumb to peritonitis from another rupture. In the third class there were perforation, general peritonitis, and marked distention, so great, indeed, that some surgeons refused to operate, as a fatal result ensued no matter what method of drainage was adopted. In determining the time to operate in any case of appendicitis the vital point was to decide whether there had been a rupture or only an inflammation around the appendix. The history of severe, sharp, sudden pain, followed by temporary improvement, should indicate the really dangerous nature of the case and the necessity of operation. If, however, there was only a history of aching and general tenderness, without any other more acute symptoms, resolution was likely to occur without operation. He would not only drain through the abdominal wound, but also make a drainage opening posteriorly through the flank. He had seen some very desperate cases end in recovery, chiefly, it seemed, because of this method of drainage.

Dr. Symns said that Dr. Morris had called attention to the fact that in the cases reported in the paper the temperature had been above the average. This was true, but he wished to repeat what he had said—viz., that the temperature was absolutely no guide in determining the severity of the attack. The pulse was about the only reliable guide that we possessed, although the expression of the face also furnished valuable information to the acute and experienced observer. He was still undecided as to the exact relation of the colon bacillus to these cases. The records would seem to show that in some cases it caused little or no disturbance, whereas in others it was the cause of very grave lesions. In cases which had gone on to the formation of large abscesses, as in his first two cases, it was unwise, in his opinion, to search far for the appendix. The reason was that the appendix was destroyed, but that it was not easily found and much manipulation was dangerous. The fourth patient had appeared to be better when he had seen him; the temperature had fallen about three degrees, and the pulse had diminished in frequency, yet this case had proved to be serious in the extreme. His experience had been that where there was sudden apparent improvement, the symptoms were entirely misleading, and should usually be interpreted as meaning rupture and abdominal sepsis.

New Inventions, etc.

A LID-ELEVATOR.

By Peter A. Callan, M.D.

In the treatment of ophthalmia, especially the gonorrhoeal variety, it is difficult to keep the eyes free from pus. I have found the modified lid-elevator represented in the following cut of great service in flushing out the upper cul-de-sac and removing the pus from the front of the eyeball. There is nothing specially new in this modification of a lid-elevator, and no such thing is intended. The shank of the instrument, together with

Miscellany.

The Neurotic Element in Pulmonary Consumption.—In a paper read before the Section in Neurology and Medical Jurisprudence at the recent meeting of the American Medical Association Dr. Thomas J. Mays, of Philadelphia, said that dis-
orders of the nervous system played a prominent part in the production of pulmonary consumption. As far back as in 1842 Chencas, in a work entitled De l’Influence de la lutte interne dans la production de la phthisie, attributed this disease directly to disorder of the pneumogastric nerves, and indirectly to an abnormal condition of the central nervous system. Dr. Mays quoted from other authors in support of the nervous theory of pulmonary consumption and said that it would be seen that this subject had interested some of the most prominent minds in the medical profession during the last fifty years. . . . At the very outset, Dr. Mays said, he would lay down the proposition that any agent or influence which had the power of disordering or interfering with the integrity of the respiratory nerves in particular, or with the nervous system in general, also had the power of producing pulmonary consumption and other forms of lung disease. In a recent canvass of the pathological literature of this subject he had found the records of over a hundred cases of phthisis in which the pneumogastric nerves or the respiratory centers had been compressed or injured or diseased in connection with syphilis, alcoholism, diptheria, measles, diabetes, multiple neuritis, locomotor ataxia, bulbary paralysis, tumors of the pons and medulla oblongata, etc. Phthisis, he said, followed in the wake of many nerve poisons. Mercurial tremor and paralysis were well known, but Kussmann’s investigations had demonstrated the fact that the majority of those who suffered from mercurial intoxication also fell victims to pulmonary consumption. Even the vitality of the children of those who suffered from mercurial poisoning was vitiated, for it was said that scrofula, rickets, and pulmonary consumption were exceedingly prevalent in the children of those who were engaged in mercury manufacture, and that it induced abortion and stillbirths among the female employees. Lead was another metal which had the power of deteriorating the nervous system and of provoking pulmonary phthisis. Statistics showed that the disease was from two to three times as prevalent among the lead-workers in Wales as it was among the farmers living in the same locality.

Among the agents which were most potent in the production of phthisis Dr. Mays placed the abuse of alcohol, and he called the attention of those to this subject who were directly engaged in the study of inebriety. It was well known, he said, that this agent exerted a poisonous influence on the nervous system, and especially on the peripheral nerves. Very frequently the nerves did not show any marked changes, but on closer examination evidence of parenchymatous degeneration with more or less interstitial neuritis was discovered; suppression of the catamenia in women, paralysis of respiration and of deglutition, and disease of the vagi and of the lungs were also observed to be of common occurrence. Syphilis was another nerve poison which was often the unsuspected cause of pulmonary disease, the typical pathological changes of which were an abundance of interstitial connective-tissue proliferation, peribronchial induration, diffuse thickening of the lobular parenchyma, syphilitic gumma, and nodular induration or broncho-pneumonia.

Whooping-cough, said Dr. Mays, was pre-eminently a specific spasmodic affection of the respiratory nerves, and various authors had ascribed it to irritation of the pneumogastric nerve. The pulmonary changes of whooping-cough were interesting, he said, because they showed the direct relationship between the disease of a nerve and that of the organ which it supplied.

Dr. Mays thought that, whatever might be the precise etiology of influenza, it was essentially a disease of the nervous system. Its morbid anatomy was principally seen in the meninges of the brain, in the spinal cord and in the peripheral nerves. Pulmonary edema, broncho-pneumonia, capillary bronchitis, and pleurisy were among its common sequelle.

Cerebro-spinal meningitis, he said, was an affection which chiefly involved the medulla oblongata and its immediate connections, and it was nearly always associated with pulmonary derangement. Epilepsy was also a disease in which the medulla oblongata was involved, and it was in the latter area, said Dr. Mays, that we should have to seek for an explanation of the ultimate and long-recognized association between this disease and pulmonary disease. Echeverria, Van der Kolk, Jobert de Lambeille, Stuart Cooper, and Rostam had reported a number of cases of epilepsy associated with pulmonary disease in which the pons Varolii, the medulla oblongata, and the vagi had been disordered.

Asthma was a spasmodic affection of the pneumogastric nerve, and it was therefore of great interest in this connection to find whether this disorder developed into more serious lung disease or not. Asthmatics, said Dr. Mays, were generally supposed to be long-lived, but he did not believe there was much clinical evidence to support this belief. There were, however, some exceptional cases which were spontaneously cured in the later years of life, but in the majority of cases the attacks inclined to become continuous, and it was to these that he referred; he believed that the tendency in such cases was a termination in pulmonary consumption.

With regard to hysteria, the author said that it implicated the respiratory organs in the form of accelerated breathing, dyspnea, aphonia, laryngeal and pharyngeal paralysis, etc., and had an innate tendency to develop into pulmonary disease either in the individual or in the offspring. Professor Grasset, he said, had found that among the brothers and sisters, grandparents and uncles and aunts of forty-four hysterical patients there had been sixty who had died or suffered from phthisis.

Idiocy also, said the author, had a powerful bearing on this subject, for in 2,380 subjects of idiocy and imbecility in the Royal Albert and Darenth Asylums in England it had been shown that a family history of consumption had existed in 674. Dr. Langdon Down, physician to the Earlswood Asylum for Idiots, stated that the statistics of London showed that the deaths from phthisis constituted 115 in 1,000 of the general mortality. His statistics at Earlswood indicated that phthisis had been the cause of death in 398 in 1,000 of the general mortality. Dr. Down had also contributed the histories of twenty families, in each of which there had been idiocy, and among the relatives 53 had suffered from consumption. Moreover, no one was surprised to find that insanity and epilepsy created a special liability to idiocy in the offspring, but it was certainly very startling, especially in the light of its supposed baracrical origin, that consumption was more powerful in this respect than any other cause which was known to lead to this disease.

The clinical association between insanity and pulmonary consumption, said Dr. Mays, had been noticed by many authors, among whom Clouston, in his Neurones of Development, made the observation that the death-rate from phthisis among the insane was four times as high as among the general population, that both diseases were very common in different members of the same family, and that heredity of phthisis might occasion insanity, and vice versa. The same author also stated, in his Lectures on Mental Diseases, that the forms of insanity commonly associated with phthisis were monomania of suspicion and melancholia. In nearly all pure cases of this kind the patients, sooner or later, died from phthisis. The most marked cases of phthisical insanity were in persons with a strong hereditary tendency to both insanity and phthisis or to the neuroses. It was surprising how often both diseases occurred in different members of the same family. The constitutional
weakness which tended to end in insanity was akin to that which tended to end in phthisis.

In the Neurologisches Centralblatt for 1890, said Dr. Mays, Dr. Bianchi had described a pneumonia which frequently occurred in paralytics, which differed clinically and anatomically from croupous pneumonia. The temperature was usually low; cough and expectoration were sometimes absent; the respiratory movements were superficial, weak, and slow; and the afflicted lung usually remained in a hepatized condition. Frequently there existed larger or smaller gangrenous foci, and nearly always, if the case was of long standing, a puriform infiltration of the alveoli and bronchi. All these manifestations simulated those of pneumonia which he had produced in rabbits and dogs by section and compression of the vagi. In a number of paralytics who had died of pneumonia he had been able to trace a primary degenerative atrophy of the vagi, and hence he believed that these pneumonias were dependent on vagus degeneration.

The subject, said Dr. Mays, was one of vast proportions, and it required a great deal of time to inquire whether the symptomatic and the therapeutic evidence was not equally favorable to the neurotic theory of phthisis as that which came from the pathological side of the question. Did not, he asked, the weakness, the easy fatique, the restless sleep, the extreme nervousness which was present in many cases, the dyspnoea, the hoarseness and aphonia, the thoracic pain, etc., indicate that the principal nature of phthisis was one of nervous exhaustion? And, therapeutically, was it not true that we got the best results from those measures and agents which proved to be the most efficient in the treatment of nervous diseases? And were not these rest, nutritious food, strychnine, electricity, hypophosphites, cod-liver oil, physreine, quinine, and remedies which appealed to and influenced the nervous system?

White's Operation for Hypertrophied Prostate.—In a letter to the editor of the Medical News, Dr. J. William White, of Philadelphia, says:

"Dr. Belchfield, in the Journal of the American Medical Association for March 9, 1895, and Dr. Bangs, in the Medical Record for April 9, 1895, published, under the leading Warning against Castration for Prostatic Enlargement, communications which, while they express some views with which I am in entire accord, contain, on the other hand, statements that hardly seem justified by the facts now before the profession.

"No one could deprecate more than I the indiscriminate performance of the operation. I suggested it with great caution, laying before the American Surgical Association the line of thought and the experimental work that seemed to me to give the idea scientific standing. More recently I wrote (British Medical Journal, January 5, 1895; Medical News, December 22, 1894) that while the evidence then existing obviously and amply justified the original suggestion, I desired to call attention to the fact that I had not made it without hesitation. I added that, 'having observed with disapprobation the indiscriminating assaults of some extremists upon the urethra, the tubes, and the ovaries, and more recently upon the appendix, I did not want to be responsible for a similar attack upon the testicles,' and that I knew that 'the step from experiment to operation is and should be a long one, and felt the responsibility involved in proposing a new operation, and especially one of this character —easy of performance, with a low mortality, and intended for the relief of a condition of enormous frequency.'

"I am still most desirous of having the operation confined within its proper limits, and to this extent am in sympathy with the gentleman mentioned.

"But when Dr. Belchfield says that while it is admitted that 'castration may cause atrophy of glands, subsidence of edema, and relief of distress, but that it will not reduce the hypertrophied connective tissue is a priori probable,' and Dr. Bangs writes that 'a theoretical operation, based upon observations upon dogs and eunuchs, in whom physiological atrophy of the prostate is said to be induced by the abrogation of its sexual function, can not reasonably be applied with the expectation of getting the same results in elderly men in whose prostates hyperplasia has already taken place,' and reiterates that the operation 'is based on theory alone,' they seem to me to ignore existing and conclusive evidence. This is now complete in every particular as regards the effect of bilateral castration on the majority of hypertrophied prostates. The experimental and theoretical stage has long since been passed. I have in my possession sections of a prostate taken from a patient that died after, but not because of, the operation, which show clearly that it does reduce the entire gland, and that the hypertrophied connective tissue shrinks and dwindles after the earlier disappearance of the glandular elements. But that this assertion may not rest on my statement I would quote Mr. Joseph Griffin, F. K. C. S., Hunterian professor of surgery and pathology in the Royal College of Surgeons, England, who has recently reported on the condition of an enlarged prostate eighteen days after double castration. He describes in detail and figures (British Medical Journal, March 16, 1895) the changes which had taken place, summing up as follows: 'In short, the cell elements first proliferate, and ultimately disappear, leaving a comparatively small amount of fibrous connective tissue in their place.... The gland, whether enlarged or normal, undergoes certain degenerative changes after removal of the testicles which lead to its conversion into a small, tough, and fibrous mass in which there are only remains of the glandular tubules and ducts.'

"As to the clinical evidence, Dr. Bangs urges that, to test the results of the operation, 'the size of the prostate should be determined by three examiners, and the examinations repeated with sufficient frequency to determine positively the size of the organ.' These conditions, which are somewhat rigid, have been complied with in all my own cases, in one of which the estimated shrinkage of the size of the prostate from that of a small orange to that of a walnut took place in a week. A half-dozen examiners confirmed this, and several hundred medical students saw the patient and learned directly from him of the concomitant and remarkable improvement in his symptoms. Dr. Lilienthal, of New York, two weeks after the publication of Dr. Bang's letter, published the report of a case (Medical Record, April 20, 1895) which so completely answers all Dr. Bang's theoretical objections as to be conclusive in itself. I may add, however, that I have now notes of similar cases to the number of nearly one hundred, in most of which all previous palliative treatment had failed, and in which the results have been equally striking. It seems to me too late to say, as Dr. Bangs does, that the relief appearing within a few hours has been too positive to be attributed to the operation itself, because, 'it hardly seems rational to believe that a hyperplastic organ in which, no doubt, there has been an increase of the connective-tissue element, should diminish in size within a few hours after castration has been performed.' The facts are against him. The hyperplastic organs do diminish in size, and often in an almost incredibly short space of time.

"Both the gentlemen who have been moved to warn the profession emphasize the possibility of mistake in diagnosis, Dr. Belchfield going so far as to say that 'whenever a case of real or supposed prostatic enlargement demands operative relief thi
MISCELLANY.

should always be an incision into the bladder." I am quite willing to admit that there must be some doubtful cases, and that in these and in a certain proportion in which the diagnosis is certain a cystotomy will often be desirable. But it is assuming altogether too much to claim that this is "always" proper. I have not found the great majority of cases of prostatic hypertrophy difficult of recognition nor of classification by combined rectal and instrumental exploration. But if I may be thought to be mistaken as to this and other similar questions raised by these gentlemen, it is hardly likely that Fenwick and Moullin and Griffiths in England, Bereskin in Russia, Helferich and Meyer and Haenel in Germany, Ramm in Norway, Watson and Warren in Boston, Halsted and Finney in Baltimore, McBurney and Stimson and Dulcher in New York, Andrews in Chicago, Souchon in New Orleans, Walker in Detroit, Haynes in Los Angeles, and dozens of other surgeons of more or less prominence have been wrong as to their diagnosis, or in saying that previous palliative treatment has failed, or unreliable in their descriptions of the rapid and sometimes astounding shrinking of the gland and disappearance of the subjective symptoms, even including long standing cystitis. They are all now on record to this general effect at any rate.

"Dr. Belfield alludes to a case in which a patient with a large prostate, 'evidently inflammatory,' and severe cystitis, was found, by suprapubic incision, to have a small calculus, previously undetected. He adds: 'Prolonged vesical drainage was followed by great reduction of the prostate and by a symptomatic cure.' He then imagines with apparent horror the status—professional and legal—of the surgeon, who might have made castration, when the calculus was subsequently discovered. This sort of argument appears to me to be misleading, as it lacks necessary detail. The age of the patient, indicating the value of the testicles from a sexual standpoint; the relation of the calculus to the enlargement of the prostate—i.e., whether cause, which would be rare, or effect, which would be common; the period indicated by the word 'prolonged'; the presence or absence of a terminal fistula; and the exact condition called a 'symptomatic cure,' should all be known before any such comparison could be drawn. I mention the case because in a gentleman, aged seventy-six years, with a large prostatic hypertrophy and a secondary calculus, which had formed after a previous litholapaxy, and which lay in a deep post-prostatic pouch, I have within the last month deliberately performed castration as a primary operation. Two weeks later, the prostate having shrunk to one sixth its former bulk, the residual urine having disappeared, and the cystitis (in spite of the presence of the calculus) having almost vanished, I crushed and evacuated the stone. The patient was sent to me by Dr. Schum, of Huntington. He went home free from all symptoms."

"Dr. Belfield says, finally, that 'the claim that double castration is safer than drainage is not, in his experience, warranted, if drainage be made either by perineal urethrotomy or suprapubic incision in deux temps; the danger in cases that really demand operative interference is the anesthetic, not the knife.' But drainage in most cases is only a palliative measure, and, if permanent, is a source of more or less continued danger and of great discomfort to the patient. Dr. Belfield has very properly described it under the head of Palliative Operations in an article that he has published elsewhere. It is not fair, therefore, to compare it at all with a measure that in properly selected cases is curative, and which thus challenges comparison with the various forms of prostatectomy. He might almost as well have written of the mortality of cathectism, which also gives great relief in some cases. As to the anæsthesia, as double castration can easily be performed within three minutes, it seems unlikely that any serious objection to the operation will prevail on that account. I have on several occasions completed it in a little less than three minutes before the class at the University of Pennsylvania, and without undue haste. In regard to the general question of mortality, however, I may be pardoned for quoting from a personal letter from Sir Joseph Lister, who writes me: 'I am glad to see from the cases that have been published that your remedy has proved so effectual in this most distressing class of patients. If I have any fault to find with you in speaking of the advantages of your procedure, it is that you seem to me to underestimate them when you say that castration is an operation of little danger. You might, I think, have truly said that if it is performed with sufficient antiseptic precautions it is entirely free from danger. The rapidity of the relief afforded seems to me as remarkable as it is satisfactory. Allow me to congratulate you cordially on this valuable addition to our art.'"

"My personal and professional regard for the gentlemen who have criticised the operation, and my knowledge of their sincerity of purpose, have led me to reply at such length; but I also have been actuated by a desire to have both its merits and demerits kept fairly before the profession. There is much yet to be determined in regard to it, especially as to the selection of suitable cases and as to its remote effects; but I think I may fairly claim that the existing evidence—experimental, pathological, and clinical—removes it from the region of theory and speculation, and demonstrates its applicability to a large proportion of cases of hypertrophy of the prostate."

"Dr. Bang's statement that 'if this theory could be proved, about one man in three, after the age of fifty, ought to submit to castration in order to prevent enlargement of his prostate,' is an extension of the operative field which must be regarded as peculiarly his own. I have as yet not considered the subject from the standpoint of early prophylaxis. As the theory is proved, it would be interesting to know how Dr. Bangs proposes to select his cases.'"
